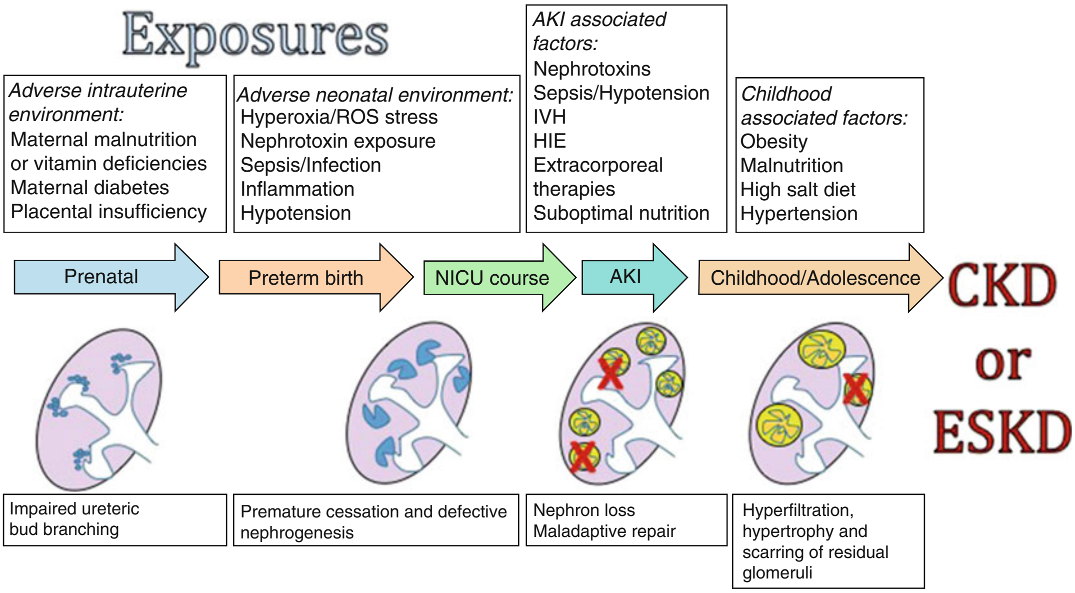
AKI as a syndrome has effects beyond the kidneys and the acute period. Emerging evidence highlights the relationship between AKI and distant organs in neonates including the brain and lungs. AKI has been associated with an increased likelihood of intraventricular hemorrhage (IVH) [123] as well as worse outcomes (death and disability) in babies with perinatal asphyxia [36]. AKI also likely has an association with lung disease and pulmonary outcomes. Recent work shows near-term/term babies with AKI have increased odds of chronic lung disease or death as well as longer duration of need for respiratory support [124]. Similarly, premature infants 29–32 weeks gestational age with AKI had higher odds of developing moderate/severe bronchopulmonary disease or death [125]. Inflammation is an underlying pathway for all these processes. Additional investigation into organ crosstalk will certainly benefit short- and long-term outcomes and highlights the importance of ongoing collaboration between neonatologists and nephrologists in the care of these fragile patients.

Long-Term Outcomes and Future Directions

The field of neonatal AKI has seen tremendous advances over the last decade in terms of our understanding of the AKI syndrome in both preterm and term infants with a range of underlying conditions and comorbidities. The ability to support these patients both medically and with KRT has also seen major advancements. Improved AKI survival for neonatal patients overall entails the need to attend to long-term kidney outcomes for these patients. CKD has been documented in AKI survivors of several conditions including TTTS and congenital heart disease [29, 62]. The long-



Exposures
Adverse intrauterine environment:
Maternal malnutrition or vitamin deficiencies
Maternal diabetes
Placental insufficiency
Adverse neonatal environment:
Hyperoxia/ROS stress
Nephrotoxin exposure
Sepsis/Infection
Inflammation
Hypotension
AKI associated factors:
Nephrotoxins
Sepsis/Hypotension
IVH
HIE
Extracorporeal therapies
Suboptimal nutrition
Childhood associated factors:
Obesity
Malnutrition
High salt diet
Hypertension
Prenatal
Preterm birth
NICU course
AKI
Childhood/Adolescence
CKD or ESKD
Impaired ureteric bud branching
Premature cessation and defective nephrogenesis
Nephron loss
Maladaptive repair
Hyperfiltration, hypertrophy and scarring of residual glomeruli

Fig. 1 Exposures across the life course lead to an increased risk of chronic kidney disease in preterm infants. Legend: Preterm infants have many exposures across their life course that predispose them to both acute kidney injury and chronic kidney disease. Awareness of the potential insults at every step may improve our ability to monitor for and mitigate these events in order to optimize kidney and overall health as these children grow. (© Reprinted with permission from Springer Nature Publishing, *Journal of Perinatology*, Harer et al. [131])

term kidney risks for premature infants related to their reduced nephron endowment have been described in several registry cohort studies [126–128] as well as some smaller, single-center retrospective cohorts [129, 130]. The attributable risk of AKI for these patients has yet to be explored prospectively and is one of the many exposures across the lifespan that put preterm infants at long-term risk for CKD (see Fig. 1) [131]. Evidence-based guidelines for appropriate follow-up of these patients are also lacking. Ongoing collaboration between neonatologists and nephrologists is critical for improving kidney function monitoring, AKI documentation, and AKI mitigation strategies whenever possible and thereby reducing chronic health risks as these children grow.

Abstract

Acute kidney injury (AKI) occurs in 5% of hospitalized children and 20–30% of children admitted to the intensive care unit (ICU). AKI is associated with poor patient outcomes, including increased risk of mortality, prolonged length of ICU and hospital stay, and prolonged invasive mechanical ventilation. Children with severe AKI and those requiring kidney replacement therapy (KRT), particularly infants and those with multiple organ dysfunction, experience mortality rates up to 70%. AKI has now been acknowledged as a common and frequently overlooked multidimensional syndrome, with additional long-lasting negative impacts on kidney health, even when function has apparently recovered after the inciting episode. The present chapter will extensively discuss how to identify and accurately diagnose an AKI episode in a timely fashion, novel research tools that are currently available to anticipate an AKI episode, risk factors that the clinician should be aware of to prevent kidney injury, and available pharmacological strategies, including management of fluid balance. An extensive section detailing technical and relevant aspects of acute pediatric dialysis is provided at the end of the chapter.

Current initiatives to guide the care of patients with AKI and focus on increasing awareness (by patients, healthcare providers, and healthcare systems) as well as on research to improve AKI diagnosis and healthcare delivery, with a goal of improving the currently poor outcomes in this particularly at-risk population, are discussed.

Introduction

Acute kidney injury (AKI) occurs in 5% of hospitalized children and 20–30% of children admitted to the intensive care unit (ICU). In the last 15 years, a large volume of literature has elucidated the potent negative impact of pediatric AKI on short- and long-term patient outcomes, highlighting the burden to patients and healthcare systems. Although proven pharmacological therapies for AKI still elude us and the approach to supporting children with severe acute kidney dysfunction, kidney replacement therapy (KRT), has not changed substantially, there has been an evolving importance placed on early identification and prevention and/or mitigation of AKI

Table 1 The kidney disease: improving global outcomes (KDIGO) definition of pediatric acute kidney injury

Stage (severity)[a,b]	Serum creatinine (SCr) criteria	Urine output criteria
1	SCr rise to 1.5 to <2 times baseline SCr within a 7 day period OR ≥ 0.3 mg/dL (26.5 μmol/L) SCr increase from baseline SCr within a 48 h period	<0.5 ml/kg/h for 6–12 h
2	SCr rise to 2 to <3 times baseline SCr	<0.5 ml/kg/h for ≥ 12 h
3	SCr rise to ≥ 3 times baseline SCr OR Increase in SCr to ≥ 4 mg/dL (353.6 μmol/L) OR Initiation of renal replacement therapy for acute kidney injury OR Decrease in estimated glomerular filtration rate to <35 ml/min/1.73 m[b] (using equation as described in text)	<0.3 ml/kg/h for ≥ 24 h OR Anuria for ≥ 12 h

[a] Patients fulfill criteria for AKI if they attain either the SCr *or* the urine output criteria
[b] The cause of AKI should be identified

and its complications. This chapter will review standard clinical evaluation and differential diagnosis of AKI, while considering ongoing novel research in diagnostic AKI biomarkers, risk stratification, and quality improvement in the context of existing guidelines [1–3], followed by a clinically practical approach to supporting patients with severe AKI using KRT. The focus of this chapter is on non-neonatal patients; a dedicated chapter will address neonatal AKI.

Definition

One of the most important research advancements in the AKI field has been the development of a standardized, multidimensional AKI definition, which led to an exponential increase in research literature describing pediatric AKI incidence and outcomes [4–8].

The Kidney Disease: Improving Global Outcomes (KDIGO) AKI Definition

In 2004, the first contemporary AKI definition was developed by an international consensus group, the Acute Dialysis Quality Initiative (ADQI) [9]. This definition evolved via several iterative changes specific to children and adults, to the currently accepted, harmonized child-adult definition, the 2012 KDIGO classification [1] (Table 1). The underlying concept is to employ changes in current biomarkers of kidney function (*increase* in serum creatinine [SCr] *or decrease* in urine output), to define AKI, and to stratify AKI severity. For example, as shown in Table 1, a child may be diagnosed with AKI if they fulfill criteria for acute SCr rise from baseline (based on a 48 h or 7 days time frame) *or* if they develop hourly urine output below a given threshold. Furthermore, depending on how high SCr rises or on how low and for how long urine output decreases, AKI severity is staged as being mild (Stage 1) or severe (Stage 2 or 3). Recently, AKI duration has been suggested as a marker of AKI severity indicated by the KDIGO classification. In this line, transient AKI (lasting less than 48 h before restoration of baseline kidney function) and persistent AKI (lasting more than 48 h) have been identified as further aspects related to the severity of the disease and associated with clinical outcomes [10].

Challenges with AKI Definition

Certain inherent limitations must be acknowledged about the current KDIGO AKI definition. First, SCr is not an ideal marker of glomerular filtration rate (GFR) for many reasons [11]. Serum creatinine concentrations are affected by muscle mass, which not only changes with age, but may also be altered by changes in nutritional status, chronic illness, or prolonged ICU stay. As GFR decreases acutely, SCr secretion by the kidney tubules increases, which may contribute to reduction in AKI ascertainment. In addition, SCr is affected by volume status, where significant volume overload can dilute SCr concentrations. This phenomenon may potentially mask SCr increase and thus also lead to underappreciation of AKI occurrence or severity. For example, imagine a patient who is postoperative cardiac surgery and receives large amounts of fluid for resuscitation, and in whom SCr concentration rises by 10 μmol/l (or ~0.11 mg/dl) from a baseline SCr concentration of 30 μmol/l (0.34 mg/dl); it is likely that the patient's SCr concentration, after aggressive fluid resuscitation, is diluted. Therefore, the true extent to which SCr has risen from baseline would be underappreciated. It has been proposed to correct SCr values for the extent of positive fluid balance, in order to appreciate what the patient's true SCr would be in the euvolemic state [12]. Simply put, the patient's SCr on a given intensive care unit day can be multiplied by a factor, which is a ratio of their fluid balance to their total body water:

Adjusted SCr = measured SCr × (1 + (fluid balance in liters from ICU admission/total body water), where total body water (liters) may be estimated as body weight × 0.6 in older children to as high as 0.8 in neonates.

The adjusted SCr may then be used to assess for AKI. AKI ascertained using this method was shown to lead to a stronger association of AKI with poor outcomes in adults and children [12, 13]. While it may seem cumbersome to perform such calculations in clinical practice, consideration of not only SCr concentration rise but also the patient's acute change in volume status may help in evaluating AKI severity in some patients.

Another potential problem in interpreting and applying SCr-based AKI definitions is the need to evaluate acute SCr rise from *baseline*; however, a child's baseline SCr is often unknown. A falsely low estimate of baseline SCr will result in overestimation of AKI. Conversely, when a more conservative or higher estimate of baseline SCr is used, some cases of mild AKI may be missed, or the presence of more severe AKI may be incorrectly assumed to be mild. To address the problem of unavailable baseline SCr values, it is recommended to estimate baseline SCr by assuming that the patient has a normal baseline GFR. In the previously healthy child, baseline (eGFR) may be estimated as 120 ml/min/1.73 m^2. Using the most recently proposed eGFR equation (GFR = 36.5 × (height in cm/SCr in μmol/l) or 0.413 mg/dl × (height in cm/SCr in mg/dl)) [14], the estimated baseline SCr may be imputed from this baseline eGFR (i.e., estimated baseline SCr = 36.5 × (height in cm/120 ml/min/1.73 m^2). In cases where height is unavailable, either a height-independent eGFR equation may be used or normative SCr values for age and sex from local laboratories may be used to estimate baseline SCr [15, 16]. Another baseline SCr challenge is deciding *which* previously measured SCr should be considered as the patient's baseline for a current AKI episode. Use of the lowest SCr in the prior 3–6 months makes widespread application of AKI definition in the research setting reasonably feasible. However, in the clinical setting, it may be better to use a baseline SCr that is more relevant for a given patient within a given scenario. For example, if 2 months prior to the current AKI episode, a patient was admitted to hospital with severe failure to thrive and a documented very low SCr value during that hospitalization, but more recently had a higher outpatient SCr value when clinically well (perhaps better nourished, higher muscle mass), it may be reasonable to utilize the more recent SCr concentration to represent this patient's baseline kidney function. In other words, in the clinical setting, it is worthwhile to take a moment and consider what the best estimate of the patient's baseline kidney function is, given their individual history and clinical characteristics.

There are also inherent challenges to the KDIGO urine output criteria. These criteria assume that urine output is being accurately and consistently measured (e.g., Stage 1 AKI is <0.5 ml/kg/h for 6–12 h). Different ICUs have varying practices in the use of indwelling bladder catheter and in recording of urine output on an hourly or quasi-hourly basis. Therefore, in order to avoid missing AKI by urine output criteria, it is important to identify patients who require more accurate urine output monitoring and to ensure this is done. Moreover, urine output rate must also be evaluated in the clinical context of hourly fluid administration to the patient. On noncritical care wards, the use of urine output criteria is clearly limited; but again, in patients who are at high risk for AKI, accurate urine output monitoring should be prioritized [3]. Despite the challenges in applying the urine output KDIGO criteria, they are important to consider as up to two-thirds of patients who fulfill urine output criteria of AKI diagnosis may be missed if only the SCr criteria are evaluated [7].

Another challenge with the KDIGO AKI definition is that it may not be as useful in all clinical contexts; they were developed for use in the critical care setting. However, not all causes of AKI will present with SCr rise or urine output decrease as suggested by this definition. For example, severe AKI due to cisplatin nephrotoxicity or other nephrotoxins which lead to urinary concentration defects will unlikely present with oliguria. In the case of cisplatin nephrotoxicity, for example, it is quite routine for patients to receive large amounts of intravenous fluids, which makes interpretation of change in SCr difficult.

What the issues above highlight is that in clinical care (as opposed to research) the KDIGO AKI definition should be used as a tool which is interpreted in the specific clinical context of the patient. It is imperative to consider each patient's history, and physical and laboratory examinations when deciding whether a patient has AKI and how severe it is, and not to base clinical decisions solely on KDIGO AKI staging. For example, while a patient may only have Stage 1 KDIGO AKI (e.g., 50% SCr rise from baseline), if they show other signs of more severe kidney injury (e.g., hyperphosphatemia, fluid overload, hyperkalemia), it would be inappropriate to make management decisions (e.g., allowing liberal fluid intake) based exclusively on the presence of Stage 1 AKI. The converse is true in cases of more severe AKI according to the KDIGO definition, but with no other evidence of AKI or risk for AKI using other clinical methods.

Epidemiology

Incidence, Disease Patterns, and Risk Factors

The incidence of AKI has been most extensively studied in critically ill children. Acute kidney injury incidence estimates range from 15 to 70% in children undergoing cardiac surgery [8, 17, 18] and 8 to 27% in noncardiac critically ill children [7, 19–21], dependent upon characteristics of patients studied. In the multinational AWARE study (Assessment of Worldwide Acute Kidney Injury, Renal Angina and Epidemiology study) of over 4000 ICU children with a predicted ICU length of stay of ≥48 h, AKI occurred in 27% of patients. Approximately half of patients with AKI developed Stage 2 or worse AKI (i.e., doubling of SCr from baseline), consistent with previous smaller studies. A preliminary analysis of a 26-center (North America and Europe) study including patients admitted ICU with confirmed severe acute respiratory syndrome coronavirus 2–positive diagnosis during the 2020 pandemic (106 children, ~45% with AKI) also showed that about half of patients with AKI developed Stage 2 or worse AKI severity [22].

Consistently, across all studies, increasing patient illness severity increases the risk of AKI. For example, in children treated with extracorporeal membrane oxygenation (ECMO), incidence of AKI approaches 75–90% [23, 24]. In the cardiac surgery setting, young age, cardiopulmonary bypass duration, and surgical complexity are important factors for AKI [25]. In noncardiac surgery ICU patients, AKI risk factors have included various markers of illness severity (e.g., vasopressors, higher illness severity/mortality scores): use of nephrotoxic medications, younger age, and oncologic diagnoses [7, 20, 21, 26]. In cardiac surgery and noncardiac surgery patients, AKI occurs early, with most AKI becoming apparent within 72–96 h of admission [19, 20, 25, 27]. Moreover, patients who have even Stage 1 AKI at the time of ICU admission are much more likely to develop more severe AKI later in admission, versus patients with no AKI at admission [7]. One two-center study showed that almost

10% of patients with AKI in the ICU do not have complete resolution of AKI (i.e., still fulfill criteria for AKI) by hospital discharge and that lack of recovery from AKI occurs more commonly in patients who develop Stage 3 AKI [28].

In non-intensive care unit patients, AKI incidence is less clear. In hospital-based studies, 5–30% of non-ICU pediatric admissions were associated with AKI; the variability in AKI rate was dependent on the frequency of SCr monitoring [29–31]. Children treated for cancer, especially with stem cell transplant, have been fairly well characterized for AKI development [32]. Most studies evaluating these patients have used SCr doubling from baseline as the AKI definition, which occurs in approximately 20% of patients after stem cell transplantation. The timing of AKI appearance in these patients is different from ICU patients, since throughout chemotherapy treatment for solid tumors and for several months after stem cell transplant, these children are exposed to repeated risk episodes for AKI from infection, radiation treatment, thrombotic microangiopathy, use of nephrotoxic medication, and intravascular volume depletion. Therefore, AKI may occur in the weeks to months after the initial hospital admission.

Nephrotoxic medication exposure is common in the hospital setting. Importantly, nephrotoxic medication exposure also represents a *modifiable* AKI risk factor and a potentially important opportunity for AKI prevention strategies. More than 80% of hospitalized children are exposed to at least one nephrotoxic medication during admission [33]. Approximately 12–30% of non-ICU children treated with aminoglycoside antibiotics develop AKI during treatment [34, 35]. In a large, single center study, 25% of children receiving aminoglycosides for at least 3 days *or* ≥ 3 nephrotoxins simultaneously developed AKI [36]. Another study demonstrated that increasing nephrotoxic medication exposure was associated with a concomitant increase in AKI risk [33]. Non-steroidal anti-inflammatory drugs have been associated with a substantial AKI rate in non-ICU hospitalized children [37]. Nephrotoxic medication associated AKI is covered extensively a dedicated chapter.

Short-Term Outcomes

A large body of literature has demonstrated that AKI is independently associated with poor patient outcomes, including increased risk of mortality, prolonged length of ICU and hospital stay, and prolonged invasive mechanical ventilation [7, 17, 21]. Children with AKI requiring KRT, particularly infants and those with multiple organ dysfunction, demonstrate mortality rates ranging from 30 to 70% [38]. However, even KDIGO Stage 1 and 2 AKI have been shown to be associated with mortality, independent of illness severity [19, 20, 27]. Two recent large studies (the AWARE study described above and a Chinese study), and several previous smaller studies in different ICU specific patient populations, have shown that AKI Stages 2 or 3 are strongly and consistently associated with ICU and hospital outcomes [7, 31]. In the non-KRT-requiring AKI setting, the mechanisms for associations with poor patient outcomes remain unclear; the less severe AKI stages do not typically cause life-threatening sequelae like hyperkalemia. One proposed pathophysiologic effect of AKI on outcomes is from evidence of organ injury “cross-talk” (cardio-renal or pulmonary-renal interactions) [39, 40]. Animal studies suggest this organ crosstalk is mediated by pro-inflammatory cytokines [41]; this is supported by data in humans, where patients with AKI have massive inflammatory mediator activation compared to healthy controls [42]. While reduction in these cytokines prevents AKI in animal models, a similar AKI prevention strategy has not been evaluated in humans to date. There is a large literature base showing that fluid overload is strongly associated with mortality and morbidity in patients with AKI who and who do not receive KRT [24, 43–47]. Thus, early treatment or prevention of fluid overload may be a modifiable, outcome-mitigating AKI complication.

Long-Term Outcomes

Animal models suggest that the link between AKI and chronic kidney disease (CKD) includes molecular or cellular triggers of chronic fibrosis and permanent kidney mass loss causing hyperfiltration mediated damage [48, 49]. In adults, even Stage 1 AKI is a risk factor for long-term CKD and mortality [50–53]. Evaluating this association in children has been very challenging because of the lack of existing large, administrative databases with post-discharge kidney function measures and because screening for CKD after an AKI episode in children has not been the standard of care. As such, AKI represents a missed opportunity to follow patients who may be at-risk for CKD development [54]. Several past single center pediatric studies, only including follow-up of AKI patients, have shown a higher incidence of long-term CKD and hypertension in children with AKI, relative to the general pediatric population. Recently, a few observational studies including AKI *and* non-AKI patients have assessed the extent to which AKI is associated with later development of CKD, hypertension, and other patient outcomes. In a retrospective two-center cohort of about 2500 ICU children, AKI during ICU admission was associated with mortality, increased healthcare utilization, CKD, and hypertension diagnosis (defined using diagnosis codes), in the 5 years after hospital discharge [4–6, 26]. A prospective two-center study of approximately 250 children showed that Stage 2 or worse AKI during ICU admission was associated with a sixfold increased risk of CKD or pre-hypertension at 6-year follow-up [55]. In non-ICU hospitalized children, one study showed that 70% of children exposed to nephrotoxins had evidence of CKD at 6-months follow-up [56]. Literature on long-term kidney outcomes of AKI after cardiac surgery is controversial. Two multicenter studies of children undergoing cardiac surgery showed that these patients have a high prevalence of hypertension and CKD (approximately 15–20%) at 4 to 5 years after surgery, but that postoperative AKI was not associated with these outcomes [57, 58]. A retrospective study conversely showed that 5-year post-cardiac surgery CKD incidence was 12% vs. 3% in patients with *vs.* without AKI [59]. Regardless of the uncertain results on the long-term impact of AKI, children having cardiac surgery are at high risk for long-term kidney disease and hypertension [60]. In children undergoing stem cell transplant, AKI was associated with CKD and hypertension up to 30 years later [61]. Although more research is needed, the data available thus far provide some information for families and justify considering post-discharge kidney follow-up in patients who develop AKI, especially Stage 2 AKI or worse.

Etiology and Approach to Evaluation

General Concepts and History-Taking

In the critical care setting, identification of a single cause of AKI is unusual as AKI is often multifactorial. In the noncritical care setting, such as the emergency room or hospital wards, it is more likely to find a single important etiology, such as nephrotoxic medication use in the patient treated for a cystic fibrosis exacerbation or a patient presenting to the emergency room with gross hematuria and hypertension, suggesting acute glomerulonephritis. While it is important to remember that most AKI occurring in hospitalized patients is due to acute tubular necrosis (ATN), it is also important to remember that ATN is a pathological diagnosis which has many causes, including severe hypoperfusion, nephrotoxic medication use, sepsis, and rhabdomyolysis [62]. Systematic identification of all potential AKI causes is crucial to provide appropriate, focused recommendations for diagnostic evaluation and avoidance of further kidney injury. Moreover, during the initial AKI evaluation, it is always important to consider and exclude, whether by history or laboratory results, causes that require immediate therapeutic intervention (e.g., rapidly progressive glomerulonephritis; hemolytic-uremic syndrome; acute interstitial nephritis, rhabdomyolysis; severe nephrotoxicity; acute obstruction; renovascular thrombosis). The overall goal of AKI evaluation should be to seek out such causes and risk factors, while ruling out less common causes of AKI.

Despite the fact that AKI is often multifactorial in nature, a useful framework for approaching AKI evaluation has been to separate AKI etiologies into three major categories: *decreased kidney perfusion* (for simplicity, renovascular events are included in this category), *intrinsic causes* (comprising a variety of kidney tissue diseases and ATN of different causes) and post-renal causes (primarily, obstruction), shown in Table 2.

The category of decreased kidney perfusion includes conditions wherein only function is altered (e.g., vomiting and intravascular volume depletion with SCr rise due to adaptive decrease in GFR, which is *fluid-responsive*) as well as conditions wherein kidney tissue may or may not be damaged (e.g., low cardiac output syndrome, nephrotic syndrome, hepatorenal syndrome, which is not *fluid responsive*; Table 2). In other words, not all causes of decreased kidney perfusion should be thought of as fluid-manageable. Decreased kidney perfusion occurs commonly in the ICU and in patients undergoing stem-cell transplants, resulting from excessive blood loss, sepsis with capillary leak, cardiac dysfunction, vomiting, inadequate fluid replacement, and burns. A detailed fluid balance history (looking for negative fluid balance) and examination for weight loss will help reveal the extent to which fluid losses may be contributing to the AKI episode and to which fluid resuscitation will benefit. A large positive fluid balance or progressive weight gain (described in more detail below) may suggest more severe AKI or point to causes associated with edema and decreased kidney perfusion (e.g., heart failure, nephrotic syndrome, hepatorenal syndrome) or of fluid redistribution from the intravascular space (e.g., capillary leak). In some cases of decreased kidney perfusion associated with volume overload, such as with nephrotic syndrome or hepatorenal syndrome, albumin infusions may help redistribute body fluid into the intravascular space, increase kidney perfusion and delivery of loop diuretics to the Loop of Henle. The category of intrinsic AKI denotes that there is damage to the kidney parenchyma or tubular, glomerular, interstitial, and vascular tissue. Intrinsic AKI thus also includes ATN which may occur due to severe decreased kidney perfusion. Other causes of intrinsic AKI (e.g., glomerulonephritis, typically associated with hypertension and hematuria) are discussed in other chapters; however, it is important to elicit any systemic symptoms (e.g., arthritis, pulmonary hemorrhage, rash, photosensitivity) which may provide insight into specific diagnoses. It is important to consider acute interstitial nephritis, which may or may not develop after exposure to an offending agent (e.g., antibiotics, proton pump inhibitors, NSAID). A detailed medication history will elucidate whether medication-induced nephrotoxicity (e.g., aminoglycosides, amphotericin-B, chemotherapeutic agents, angiotensin converting enzyme inhibitors, calcineurin inhibitors,

Table 2 A simple classification for causes of AKI, with some examples of causes

Decreased kidney perfusion	Intrinsic	Post-renal
Hypotension or reduced intravascular volume Dehydration/hypovolemic shock due to GI, urinary, or other losses Hemorrhagic shock Sepsis *Reduced colloid pressure* Nephrotic syndrome Liver failure Malnutrition/hypoalbuminemia Sepsis/capillary leak Burns *Reduced cardiac output* Cardiogenic shock due to heart failure, tamponade, etc. *Vascular* Renal vein stenosis/thrombosis Renal artery stenosis/thrombosis Malignancy with secondary mass effects on vessels	*Glomerular* Glomerulonephritis *Tubular (includes ATN)* Hypoxic-ischemic injury Hemolysis Rhabdomyolysis Tumor lysis syndrome Toxins *Interstitial* Pyelonephritis Acute interstitial nephritis *Vascular* Hemolytic uremic syndrome Thrombosis or stenosis of renal vessels (artery or vein) Malignant hypertension	*Renal obstruction with solitary kidney* Ureteral-pelvic junction Ureteral stenosis Ureteral-vesical junction Malignancy with secondary mass effects *Bilateral ureteral obstruction* Stones Malignancy *Urethral obstruction* Posterior urethral valves Catheter obstruction

radiocontrast agents, discussed in a dedicated chapter) may be contributing to the current AKI episode. Non-medication nephrotoxic causes include myoglobin (i.e., rhabdomyolysis) and plasma free-hemoglobin (e.g., with severe hemolytic anemia or during ECMO).

Physical Examination

The physical exam may provide evidence of the cause of AKI. A rash or arthritis may suggest vasculitis, whereas ascites or jaundice may suggest hepatorenal syndrome. Low blood pressure and poor perfusion will strongly suggest ischemic ATN. The physical exam also helps to evaluate the severity of fluid overload associated with AKI. Correlating changes in oxygen needs with changes in fluid balance may help determine the extent to which fluid overload is impeding adequate oxygenation and ventilation [43]. Careful attention to magnitude of fluid overload is mandatory in patients with AKI due to its prognostic significance (discussed above) and implications on management. Different methods for fluid overload assessment based on calculating changes in daily weights and fluid balance as a percentage of estimated dry weight have been proposed [24, 63, 64]. For critically ill patients, the most commonly reported formula uses the difference in fluid output from fluid intake since ICU admission, as a percentage of the patient's estimated dry weight, using the following formula to quantify the degree of fluid overload:

Fluid overload (%) = (fluid in liters – fluid out liters)/weight in kg * 100% [64].

In units which perform daily weight measures, an alternative weight-based formula for calculating fluid overload may be used:

Fluid overload (%) = [*current weight (kg) – ICU admit weight (kg)*]/*admit weight (kg) * 100*

Fluid overload greater than 10–15% has been associated with poor outcomes in critically ill children [65]. Worsening of fluid overload, despite attempts at diuresis, may imply the impending need for KRT.

Laboratory Investigations

Laboratory investigation can help elucidate specific AKI causes as well as evaluate its severity. Table 3 shows suggested laboratory investigations in AKI. Urine examination assesses for evidence of glomerulonephritis (hematuria, red blood cell casts, white blood cell casts), interstitial nephritis (pyuria, urine eosinophils), or renovascular thrombosis (e.g., isolated hematuria without casts, in the presence of hypertension). Patients with ATN may have granular or muddy brown casts. Other laboratory investigations listed in Table 3 are helpful to assess for other concurrent causes of AKI. For example, the complete blood count and smear are essential to assess for thrombotic microangiopathy (low hemoglobin, thrombocytopenia, and schistocytes). A kidney ultrasound is often performed for first AKI evaluation, to evaluate anatomy and determine if obstruction or renovascular thrombosis is present using Doppler imaging evaluation. With ATN, the kidneys may appear normal on ultrasound examination, or may be enlarged and/or hyperechogenic with or without elevated resistive indices on Doppler interrogation. Kidney biopsy is typically reserved for patients in whom acute intrinsic renal diseases other than ATN may be suspected (e.g., glomerulopathies due to different causes, presenting with significant proteinuria and/or hematuria; acute interstitial nephritis presenting with severe hypertension, pyuria, and consistent clinical history; patients presenting with a suspected systemic disease known to be associated with kidney disease, such as lupus). On kidney biopsy, ATN may be associated with different histopathological findings depending on severity and cause of ATN (reviewed in detail in the following reference) [66]. In general, the glomerular compartment is relatively spared and injury is evident in the tubular compartment and potentially the interstitium. Histopathological evidence of tubular injury may be quite patchy or may appear quite subtle, especially with ischemic ATN; with direct tubular toxicity, the tubular epithelial cell changes

Table 3 Laboratory Investigations for AKI

Urine Testing
Urinalysis and Urine Culture Dipstick testing for hematuria, proteinuria, signs of infection/inflammation (leukocytes, nitrites) or of interstitial nephritis (leukocytes) Urine culture should be collected by catheterization (non-toilet trained children) or midstream sample (toilet trained children)
Urine Microscopy Muddy brown or granular casts is suggestive of acute tubular necrosis Predominant leukocytes is suggestive of acute interstitial nephritis Urinary eosinophils for suspected acute interstitial nephritis Red blood cell casts and/or white blood cell casts are suggestive of acute glomerulonephritis
Proteinuria Total (including glomerular and tubular) protein (protein:creatinine ratio or 24-h urine collection if proteinuria appears significant) Glomerular proteinuria (albumin:creatinine ratio) Tubular proteinuria (ß2-microglobluin, as may be elevated with interstitial nephritis)
Fractional Excretion of Sodium Fractional Excretion of Sodium (FeNa) (%) = (Urine Na/Plasma Na)/(Urine Creatinine/Plasma Creatinine) * 100 *Ensure that units of measurement for urine and plasma Na and for urine and plasma Creatinine are the same* FeNa <1% suggests decreased kidney perfusion with adaptive decrease in GFR/fluid-responsiveness FeNa >2% suggests intrinsic AKI (e.g., ATN)
Fractional Excretion of Urea^{b} Fractional Excretion of Urea (FeUrea)^{b} (%) = (Urine Urea/Plasma Urea)/(Urine Creatinine/Plasma Creatinine) * 100 *Ensure that units of measurement for urine and plasma Na and for urine and plasma Creatinine are the same* FeUrea <35% suggests decreased kidney perfusion with adaptive decrease in GFR/fluid-responsiveness FeUrea >50% suggests intrinsic AKI
Blood Tests
Serum creatinine and document or estimate baseline serum creatinine to calculate AKI severity • Consider correcting serum creatinine for fluid status if there is fluid overload: Corrected Creatinine = Serum Creatinine [1 + (Net Fluid Balance since admission in liters/Total Body Water in liters)]
Further investigations for severity and etiology of AKI Complete blood count If anemia and thrombocytopenia, concern for TMA: send LDH, bilirubin, haptoglobin, blood film (smear). Blood urea nitrogen Sodium, potassium, chloride, bicarbonate, ionized and total calcium, magnesium, phosphate, blood gas (evaluate severity of AKI) Albumin Consider: liver enzymes and INR (if suspect hepatorenal syndrome); auto-immune/vasculitis work-up directed by history and physical exam; drug levels for patients on nephrotoxic medications which can be measured in the blood. If concern of rhabdomyolysis, send serum creatine kinase, urine myoglobin
Tests, if abnormal, suggest acute on chronic kidney disease Iron studies, including ferritin, iron, transferrin, total iron binding capacity, and calculation of percent transferrin saturation (TSAT) Intact PTH 25-[OH]-Vitamin D3
Imaging
Diagnostic Imaging Includes renal ultrasound with Doppler – kidney anatomy, obstruction, vascular thrombosis CT or MR imaging in cases with suspect mass or to rule out stones, as clinically indicated. Other investigations depend on etiology including VCUG, renal MAG3 scan, and DMSA renal scan
Other
Renal Biopsy
AKI Biomarkers (currently commercially available tests for NGAL and for TIMP-2*IGFBP-7 are available)

(in particular proximal tubule) may be more evident. Findings of tubular injury include, but are not limited to: epithelial cell swelling, loss of brush border; cell swelling with vacuolization, characteristic of tubular toxicity, often due to drugs; with more severe injury, flattening of epithelial cells with evidence of mitosis (i.e., cellular regeneration); interstitial edema and/or mild inflammation; different types of casts seen in the tubular lumens.

Importance of Considering Clinical Setting During AKI Evaluation

When evaluating AKI in specific clinical settings, it is important to consider the relevant pathophysiology of AKI within that setting. For example, in the setting of sepsis-induced AKI or cardiac surgery-associated AKI, where ATN may be prominent, oliguria is typical. However, patients treated with cisplatin or ifosfamide for cancer may develop significant direct renal tubular injury, but may not present in the typical manner of other causes of ATN. The primary insult is tubular injury leading to severe abnormalities in tubular electrolyte transport function and urinary concentration. Thus, these patients will primarily present with severe electrolyte disturbances *without* oliguria. Similarly, cardiac patients with a history of prolonged low cardiac output state and kidney hypoperfusion (cardiorenal syndrome) with consistent use of diuretic therapy may have subtle creatinine increase without modifications in urine output. A similar presentation may occur in the setting of aminoglycoside nephrotoxicity. It is important to appreciate these differences, foresee potential complications and not understate the importance of the AKI episode, simply due to lack of oliguria.

Evaluating Serum Creatinine Rise: Distinguishing Adaptive Renal Response from True Tubular Injury

A common diagnostic dilemma occurs when patients present with a rise in SCr associated with evidence of decreased kidney perfusion. Some patients simply require fluid administration to re-perfuse the kidneys, leading to quick return of SCr concentrations to baseline values; these patients likely do not have significant tubular or *structural* injury. Rather, reduction in GFR resulting in the SCr increase is adaptive, to offset the reduction in kidney perfusion. When kidney hypoperfusion is severe, ATN may develop and overly aggressive fluid administration may contribute or lead to fluid overload and respiratory compromise. The ability to differentiate purely functional SCr alterations from structural injury is currently limited, though research in kidney injury biomarkers will likely fill this knowledge gap in coming years, as described in the next section. Until the use of biomarkers of kidney structural damage is widely available, examination of urine microscopy for muddy brown casts may indicate ATN. Calculating the fractional excretion of sodium or urea may also help differentiate between elevations in SCr due to renal hypoperfusion *vs.* ATN (detailed in Table 3) because the inability of tubules to avoid sodium losses or excessive urea losses conceptually implies their structural damage:

Fractional excretion of sodium:
$$(\text{Urine sodium} \times \text{SCr}/\text{Serum sodium} \times \text{Urine creatinine}) \times 100.$$

The fractional excretion of urea is similarly calculated. Sodium and urea fractional excretion should be low ($<1\%$ for sodium and $< 35\%$ for urea) with fluid-responsive elevations in SCr, whereas with ATN, fractional excretion will be higher ($>2\%$ for sodium and $> 35\%$ for urea, Table 3). The fractional excretion of urea may be less affected by diuretic use, whereas fractional excretion of sodium is unreliable in patients receiving diuretics. Blood urea nitrogen (BUN) elevation out of proportion to SCr may also indicate kidney hypoperfusion as an important contributing factor to AKI; however it is important to remember that BUN can be elevated in states of gastrointestinal bleeding and corticosteroid exposure, and does not rule out the presence of ATN.

A recent study proposed a novel way to help differentiate patients with elevation in SCr fulfilling criteria for Stages 1 or 2 AKI, who will *not* progress to a more severe AKI stage from those who will progress [67]. This diagnostic method is referred to as *the Furosemide Stress Test*: a standard dose of 1 to 1.5 mg/kg of furosemide is administered and urine output response is evaluated. In adults, patients with <200 ml of urine output in the first 2 h of the test had the highest risk for severe AKI [67]. Single studies evaluating the furosemide stress test in pediatric populations have shown similar promising results [68, 69].

Many patients have elevated SCr at the time of ICU admission; but not all these patients will go on to develop more severe AKI. The *Renal Angina Index* is a scoring system applied at ICU admission, which was developed and validated to predict risk for severe AKI in ICU children, by combining known AKI risk factors (transplant recipient; mechanical ventilation or vasopressor support) and functional evidence of injury (i.e., SCr rise and fluid overload %; Table 4) [70]. Renal Angina Index derivation and validation studies showed that a score ≥ 8 was highly predictive of the presence of $\geq$ Stage 2 AKI on ICU day 3 [71, 72]. Although the Renal Angina Index has been mainly used for prognostication in the research setting, it highlights the importance of identifying patients at high risk for severe AKI early after ICU admission, which may have significant implications on preventive and anticipatory management.

AKI Injury Biomarkers

In the last 15 years, a large amount of research has been performed to evaluate new diagnostic tests of AKI. As described above, the *functional markers* SCr and urine output do not adequately distinguish presence or absence of actual kidney tissue/structural injury. Moreover, SCr and/or urine output change late in the pathophysiology of AKI, up to 72 h after injury has occurred [73]. These characteristics pose significant challenges to successful interventions to prevent or treat AKI. Serum Cystatin C (CysC) (a non-glycosylated, 13.3-kDa protein belonging to cystatin protease inhibitors, normal value 0.65–0.9 mg/l) is a marker of GFR in a similar way to SCr. Many centers around the world now include CysC measurement as a standard biochemistry test. Cystatin C has many advantages over SCr for evaluation of kidney function, including concentrations do not vary substantially with age, muscle mass, diet, and physical activity [74]; CysC is primarily excreted by glomerular filtration; it undergoes minimal tubular secretion and in the urine it is degraded by proximal tubular

Table 4 Summary of the renal angina index for predicting severe AKI on day 3 of ICU admission[a]

RISK	**Risk Criteria**		**SCORE**
	ICU admission		**1**
	Solid organ or stem cell transplantation		**3**
	Mechanical ventilation or vasoactive support		**5**
INJURY	**ICU admission SCr[b] divided by Baseline SCr**	**% Fluid Overload**	**SCORE[c]**
	Decreased or no change	<5%	**1**
	>1–1.49	5–10%	**2**
	1.5–1.99	10–15%	**4**
	≥2	>15%	**8**
			Renal Angina Index Score ***How to calculate:*** Risk Score (1, 3 or 5) × Injury Score (1, 2, 4, or 8). Score range: 1 to 40 **Renal Angina = Score ≥ 8**

[a] Renal angina index score is calculated 12 h after ICU admission
[b] The highest SCr between ICU admission and 12 h after admission is used
[c] The worst of the SCr/Baseline and %Fluid Overload score is used

cells [74]. These attributes make CysC an ideal and likely more accurate marker of GFR than SCr is [14, 75, 76]. However, the extent to which CysC is more than useful than SCr is to identify *acute changes* in GFR, such as with AKI, is still unclear. Some studies in ICU patients, including those undergoing cardiac surgery, have shown that CysC rises with AKI before SCr does [77–79]. Recently, including acute CysC changes in AKI evaluation has been shown to be a possibly useful adjunct test to predict AKI outcomes in children treated with stem cell transplant [80]. However, CysC remains a *functional marker* (i.e., of GFR), rather than a marker of kidney tissue/structural injury.

Translational research using different animal models of ischemic and nephrotoxic AKI has identified several novel urinary proteins of kidney injury [81–86]. These proteins are either secreted in urine as a result of renal tubular cell injury and extrusion from the cell cytoplasm, or are somehow involved in AKI pathophysiology or cellular repair, allowing for early identification of tissue injury, *before* function is impaired (i.e., before SCr rises or urine output decreases). Table 5 summarizes only some of the biomarkers which have been studied, with reference to their origins and proposed role in AKI [86–100]. AKI biomarkers of tissue injury may be broadly classified into tubular damage biomarkers (mainly filtered urinary proteins normally reabsorbed by uninjured proximal tubular cells, such as beta-2 microglobulin or *N*-acetyl-beta-D-glucosaminidase), biomarkers whose genes are induced or downregulated by AKI (e.g., neutrophil gelatinase-associated lipocalin [NGAL]; interleukin-18 [IL-18]; kidney injury molecule-1 [KIM-1]), or biomarkers of cell cycle arrest (e.g., tissue-inhibitor of metalloproteinases-2 [TIMP-2]; insulin-like growth factor binding protein-7 [IGFBP-7]). This chapter does not discuss an

Table 5 Some recently studied biomarkers of AKI which are upregulated in response to injury (This biomarker list is not exhaustive, but merely represents some recent or commonly published biomarkers in pediatrics. Many more AKI biomarkers have been discovered and undergone initial human validation study)

Biomarker	Kidney injury location	Mechanism of action upon injury
Neutrophil gelatinase-associated lipocalin (NGAL) **commercially available assay*	Proximal tubules, likely distal	Upregulated, released in urine/plasma. Action unknown, appears protective: chelates iron from damaged tubules preventing free radical formation, less cell death
Interleukin-18 (IL-18)	Proximal tubules	Produced by proximal tubule cells: upon injury, caspase-1 cleaves pro-Il-18 inactive form to active form which exhibits pro-inflammatory properties
Kidney injury molecule-1 (KIM-1)	Proximal tubules	Promotes apoptotic and necrotic cell clearance: upregulated and shed into the urine and extracellular space
L-type fatty acid binding protein (L-FABP)	Proximal tubules	Upregulated, binds lipid hydroperoxides and other reactive oxygen species
Hepcidin-25 (Hep-25)	Thick ascending limb, collecting ducts. Cellular: apical cell pole.	Inhibits intestinal iron absorption and release from macrophages/hepatocytes; upregulated by inflammation
Product of tissue inhibitor of metalloproteinases-2 *and* Insulin-like growth factor binding protein-7 (TIMP-2 X IGFBP-7) **commercially available assay*	Two G1 cell cycle arrest biomarkers: TIMP-2 is a metalloproteinase inhibitor; IGFBP7 is an insulin-like growth factors binding protein	Expressed in renal tubular cells with injury, leading to blocking the effects of cyclin-dependent protein kinase complexes on cell cycle promotion, G1 cell cycle arrest

exhaustive list of AKI biomarkers being studied.

Tubular damage biomarkers have demonstrated modest success at best for AKI diagnosis prior to SCr rise. Biomarkers induced or downregulated with renal tubular injury have variably shown the highest promise for early AKI diagnosis. Pediatric AKI biomarker research to date has focused mostly (but not only) on urine NGAL, IL-18, KIM-1, and liver-type fatty acid binding protein (L-FABP) [99]. Several studies in children undergoing cardiac surgery, admitted to the critical care unit, treated with intravenous contrast or other clinical AKI scenarios (including patients undergoing stem cell transplant, treated with chemotherapies or other nephrotoxins), demonstrate these urine biomarker concentrations increase up to 48 h prior to SCr in patients with AKI and/or predict poorer outcomes and morbidity [80, 86, 93, 95–97, 101–104]. Furthermore, increasing elevations in these biomarkers may predict development of worse AKI severity [80, 91, 103]. Until recently, one of the challenges in moving past the research phase of novel AKI biomarkers has been the lack of rapid testing methods or of biomarker measurement methods available for use on standard biochemistry platforms. NGAL is now available for measurement using standard lab platforms and several centers across the world have begun utilizing urine NGAL measurement in clinical care. This is fortunate, as urine NGAL is the AKI biomarker which has the strongest evidence for early detection of AKI in children, especially in children undergoing cardiac surgery. Although more research is needed to identify optimal thresholds for AKI diagnosis in children with AKI from different causes, proposed urinary NGAL diagnostic concentration thresholds for mild AKI and for severe AKI are $\geq$50 ng/ml and $\geq$ 150 ng/ml, respectively [80, 105, 106]. The multiplicative product of urinary concentrations of TIMP-2 and IGFBP-7 (TIMP-2*IGFBP-7) has been evaluated for early AKI diagnosis in critically ill adults [99, 100]; a commercially available rapid testing assay (the "Nephrocheck®") is now available and approved in the USA for predicting AKI in critically ill adults at ICU admission. Several studies have recently been performed in children undergoing cardiac surgery and other patient populations, showing promise for clinical application in children [100, 104, 107, 108]. Hopefully, ongoing validation studies and studies determining the best diagnostic thresholds in children will be expedited by the fact that a commercially available assay is available. Although current AKI biomarker utility is still mainly used for research, future AKI definitions will likely incorporate markers of kidney tissue injury in addition to markers of kidney function (i.e., SCr and UO) [109, 110]. This will result in a huge change in how AKI is approached, providing the ability to differentiate fluid-responsive AKI or quickly reversible AKI or benign forms or renal dysfunction from true acute kidney tissue injury and the ability to prognosticate progression of AKI to more severe forms.

An important concept in moving toward clinical application of novel AKI biomarkers is that these diagnostic tests are most likely to be useful when applied to patients who are *at substantial risk* for AKI, versus widespread non-selective application; that is, testing the right patient at the right time. One major advancement in this field has been combing application of AKI risk scores, like the Renal Angina Index (described above), with novel AKI biomarkers. When AKI biomarkers (particularly, NGAL) were measured in children with ICU admission Renal Angina Index score $\geq$ 8, prediction of Stage 2 or worse AKI by Day 3 of ICU admission drastically increased, being near perfect [101]. In another example, when the clinical risk assessment provided by the Furosemide Stress Test was combined with urine AKI biomarkers, prediction of severe AKI development was significantly improved [111]. Once new AKI biomarkers become approved for bedside clinical testing, they may also be useful to show the effectiveness or toxicity of novel AKI therapies.

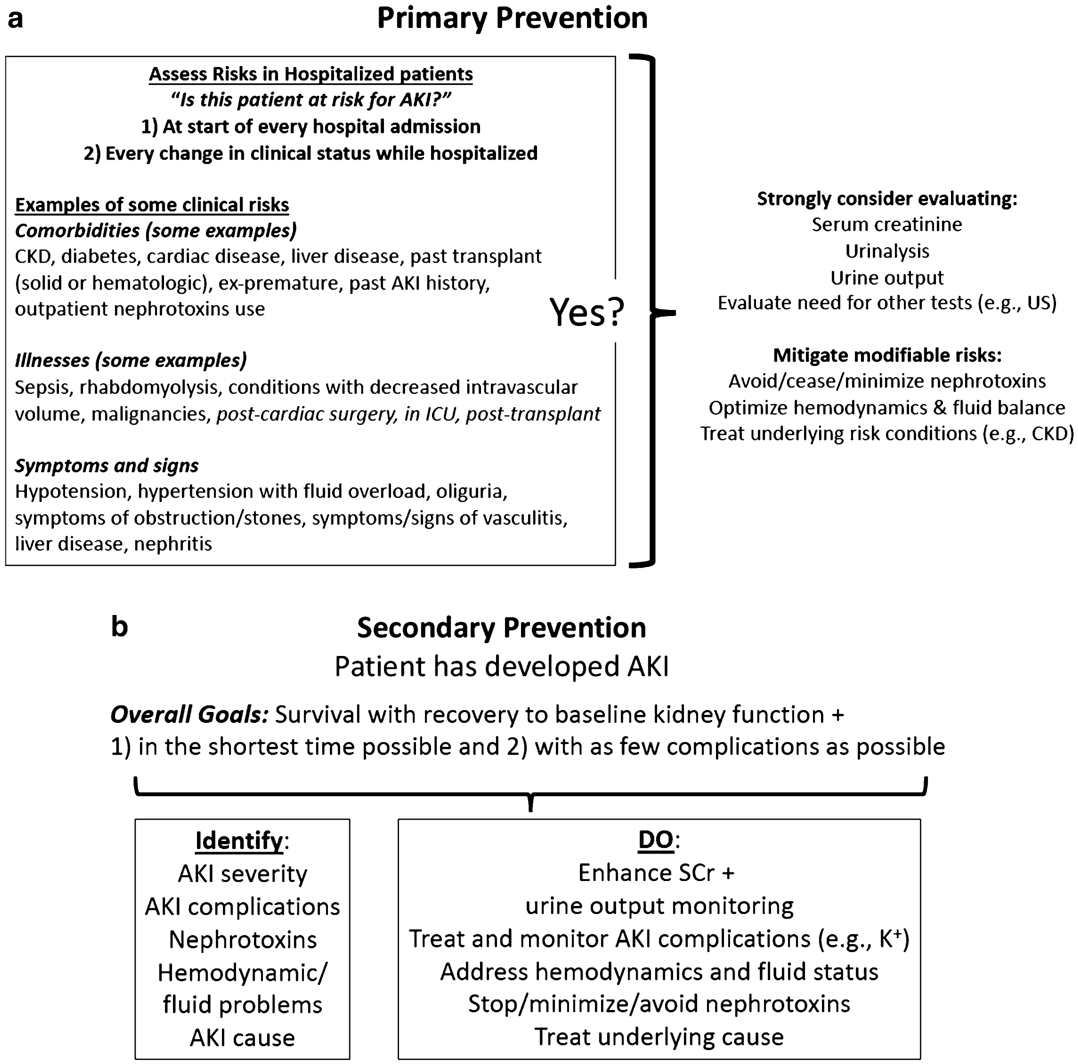
Management

Prevention

Ideally, measures to prevent AKI occurrence by avoiding risk factors in susceptible patients should be instituted before AKI develops (primary prevention). However, unfortunately, the pediatric nephrologist often becomes involved in patients with AKI well after the injury has occurred. A recent study in children treated with aminoglycosides for a cystic fibrosis pulmonary exacerbation, demonstrated that increasing SCr monitoring during therapy (daily, versus at the medical team's discretion), was associated with an increase in detection and earlier identification of AKI [35]. This makes sense; if kidney function is monitored more closely in at-risk patients, the likelihood of detecting AKI will increase. Potential benefits include earlier diagnosis, more timely avoidance of inappropriate fluid administration and other AKI risk factors (e.g., other nephrotoxins), and possibly reduction of ultimate AKI severity. Thus, the nephrologist may work with other medical services to identify specific patients at risk for AKI and suggest renal function monitoring strategies with the goal of early identification and further kidney injury avoidance. Another study demonstrated that in non-critically ill hospitalized children, the presence of three or more nephrotoxins increased the risk of developing AKI [33]. Based upon this work, one study implemented an electronic health record (EHR)-guided program which included daily SCr monitoring program and pharmacy-guided recommendations for all non-critically ill patients receiving three or more nephrotoxic medications or an intravenous aminoglycoside for more than 3 days [36]. This program, discussed in detail in chapter "Nephrotoxic Medications," is called the "Nephrotoxic Injury Negated by Just-in time Action (NINJA)" program; at the initial center where NINJA was developed, adherence to appropriate and recommended SCr monitoring was greater than 99%, and they observed a 42% reduction in AKI days. In a recently published nine-center NINJA application and validation study, an overall 24% reduction in nephrotoxic-associated AKI rate was observed [112]. In centers where such a systematic, EHR-guided program may not be feasible, the nephrologist may still significantly impact AKI avoidance by consulting with other medical specialty colleagues to provide education regarding nephrotoxin avoidance and kidney function monitoring or minimization.

Other attempts have been made to leverage EHRs to predict imminent AKI or to alert regarding its early detection [113, 114]. Electronic "sniffers" or "clinical decision supporting systems" have been evaluated as tools to achieve primary and secondary AKI prevention. Additionally, EHR-based models may contribute to the stratification of patients in whom further diagnostic measures could be performed (e.g., AKI biomarkers), enhancing the synergy between two predictive modalities and improving the respective predictive accuracy [115]. Studies including thousands of hospitalized patients were able to show the efficacy of these systems in reducing severe AKI incidence by simply increasing clinicians' awareness regarding the presence or the worsening of kidney function [116, 117]. The role of these systems in critically ill children is currently unknown but a wise application of organ failure alerting will possibly be a common application in electronic charts in the years to come.

Measures to prevent *further* kidney injury once AKI is present (secondary prevention) are instrumental in AKI management, namely, by avoidance of [1] hypotension (including provision of appropriate inotropic support) and [2] nephrotoxic medication use, with re-evaluation of the need for nephrotoxins and closely following serum concentrations when possible. A recent consensus publication from the 22nd Acute Dialysis Initiative conference [3], which was focused on quality improvement in AKI, nicely outlined several potential guidelines and recommendations for primary and secondary prevention of AKI, summarized briefly in Fig. 1. This document highlights the importance of (1) primary prevention (Fig. 1a): assessing *all* hospitalized patients for *risk* of developing AKI (determining whether their clinical history, pre-admission medications, acute illness, or other factors place them at risk for AKI) and if they are at risk, ensuring that appropriate measures are taken to *diagnose* AKI (e.g., SCr monitoring, urine output measurement); and (2) secondary prevention (Fig. 1b): Once AKI is diagnosed, to ensure that the severity of AKI is appropriately evaluated and that measures are actively taken to diagnose the cause, minimize further injury and promote recovery.



a
Primary Prevention
Assess Risks in Hospitalized patients
"Is this patient at risk for AKI?"
1) At start of every hospital admission
2) Every change in clinical status while hospitalized
Examples of some clinical risks
Comorbidities (some examples)
CKD, diabetes, cardiac disease, liver disease, past transplant (solid or hematologic), ex-premature, past AKI history, outpatient nephrotoxins use
Illnesses (some examples)
Sepsis, rhabdomyolysis, conditions with decreased intravascular volume, malignancies, post-cardiac surgery, in ICU, post-transplant
Symptoms and signs
Hypotension, hypertension with fluid overload, oliguria, symptoms of obstruction/stones, symptoms/signs of vasculitis, liver disease, nephritis
Yes?
Strongly consider evaluating:
Serum creatinine
Urinalysis
Urine output
Evaluate need for other tests (e.g., US)
Mitigate modifiable risks:
Avoid/cease/minimize nephrotoxins
Optimize hemodynamics & fluid balance
Treat underlying risk conditions (e.g., CKD)
b
Secondary Prevention
Patient has developed AKI
Overall Goals: Survival with recovery to baseline kidney function +
1) in the shortest time possible and 2) with as few complications as possible
Identify:
AKI severity
AKI complications
Nephrotoxins
Hemodynamic/ fluid problems
AKI cause
DO:
Enhance SCr + urine output monitoring
Treat and monitor AKI complications (e.g., K+)
Address hemodynamics and fluid status
Stop/minimize/avoid nephrotoxins
Treat underlying cause

Fig. 1 (**a**) Proposed approach to primary and secondary hospital-AKI prevention, Modified from the Acute Dialysis Quality Initiative Consensus Statement. (**b**) This simplified approach was modified from the Acute Dialysis Quality Initiative 22nd conference consensus publication on quality improvement targets in AKI. A pediatric-specific document will be developed in coming years

Fluid Management

Careful attention to fluid management is critical to mitigate AKI complications. Patients with decreased kidney perfusion and adaptive decrease in GFR as the cause for SCr rise will often respond to fluid resuscitation, whereas patients with ATN should be treated with volume restriction, to prevent development of worsening fluid overload, or may require diuretics to mitigate fluid overload. Thus, fluid prescription for children with AKI is directed by the individual clinical situation. Generally, a safe starting point, assuming fluid resuscitation has been performed, is to provide insensible losses (400 ml/m^2 of body surface area in patients with normal basal metabolic rate, higher in febrile patients and lower for ventilated patients who have lower respiratory losses), plus replacement of ongoing losses (urinary, gastrointestinal, chest tubes). This fluid prescription will generally be appropriate to *maintain* current volume status in patients who require fluid restriction and in those with polyuria, but will not be appropriate in the setting of acute volume depletion. To promote the achievement of negative balance in patients exhibiting fluid overload, less than the total urine output may be replaced. After a period of observation, a fixed daily fluid prescription may be prescribed, while ensuring frequent re-evaluation. Because of the important potential deleterious effects of fluid overload on outcomes described above, it is vital to always remember to think of overly aggressive fluid provision in patients with AKI as potentially detrimental. Judicious administration of fluids coupled with very frequent re-evaluation of volume status allowing for timely initiation of fluid removal when needed may lead to avoidance of these negative fluid overload effects.

Prospective randomized studies of adult patients at risk for ATN have shown that intravenous furosemide is unlikely to reverse oliguria and large retrospective studies in adults have not demonstrated improvements in outcomes in patients with AKI [118, 119]. The KDIGO AKI guideline recommends using diuretics to manage fluid overload and not to prevent or treat AKI [1]. However, maintaining urine output clearly facilitates the delivery of appropriate nutrition, without further worsening fluid overload. Typically, loop diuretics are used to maintain urine output (most commonly furosemide, but bumetanide is often used as well) either as an intermittent bolus or as a continuous infusion. Especially if there is evidence of benefit to maintaining urine output, adding a thiazide diuretic or metolazone, which targets the distal segment of the renal tubules, may be helpful. Use of diuretics to maintain urine output needs to be balanced with careful and frequent evaluation of volume status and frequent evaluation for success or non-success to avoid delay in KRT initiation. In other words, if diuretics are being used to maintain urine output in order to provide nutrition and avoid fluid overload, then these two desired outcomes should be measured and evaluated frequently. Another situation where volume control is crucial (i.e., critical need to avoid volume overload) is when “congestive” kidney dysfunction is present (e.g., patients with right ventricular dysfunction, severe congestive heart failure, or some children after complex cardiopulmonary bypass surgery). In these patients, elevated central venous pressure can significantly contribute to reduced GFR and likely to kidney injury, which strongly suggests that aggressive and timely management of volume overload (i.e., diuresis and/or KRT) may contribute to prevention and/or recovery from AKI [120, 121]. In such patients, close communication between the nephrologists and intensivist is crucial.

Electrolyte Management

Electrolyte management in AKI includes both acute and subacute management and is also dependent on the cause of AKI. Patients with oligo-anuric kidney failure or severe ATN should not receive potassium or phosphorus unless they exhibit hypokalemia or hypophosphatemia. Sodium intake should be restricted to 2–3 mEq/kg body weight per day, together with fluid restriction, to prevent sodium and fluid retention with resultant hypertension. Conversely, patients with AKI secondary to nephrotoxic medications or interstitial nephritis may demonstrate polyuria, placing them at risk for fluid and electrolyte losses. Polyuria in this setting may lead to salt or other electrolytes wasting, and may require higher administration than normal. In order to safely achieve these goals, it is ideal to request insertion of a urinary catheter and obtain weights and serum electrolyte levels at least daily.

Acute non-dialytic management of electrolyte problems due to AKI includes management of severe acute hyperkalemia which can lead to deadly cardiac arrhythmias. Intravenous calcium may be used to mitigate these effects, and measures to increase potassium entry into the cells, such as sodium bicarbonate (if the patient is acidotic), beta-2 agonists or insulin with dextrose, can be given. Severe hypocalcemia may also cause cardiac conduction defects and should be corrected judiciously, especially in the setting of severe hyperphosphatemia, to avoid crystal formation. Moreover, the administration of sodium bicarbonate for correction of hyperkalemia may exacerbate hypocalcemia. Hyperphosphatemia, if not severe and not associated with severe hypocalcemia, may be managed with phosphate binders and restriction.

Pharmacological Therapy

There is no proven specific pharmacologic treatment for AKI. However, preservation of renal perfusion with appropriate inotropic agents is essential in critically ill patients unresponsive to volume repletion [122]. The effects of dopamine, a commonly used inotropic agent in children, are varied and complex, leading to controversy with respect to its utility in the setting of AKI. Dopamine increases renal plasma flow and sodium excretion at low or so-called renal doses of 0.5 to 2 mcg/kg/min. However, these effects are short-lived [123]. At increasing doses, dopamine binds beta- and then alpha-adrenergic receptors, rendering it difficult to ascertain whether any observed renal benefit from dopamine occurs as a result of its dopaminergic or inotropic effect. Well-designed prospective randomized studies of adult patients at risk for ATN have seriously called into question the utility of "renal-dose" dopamine in reversing oliguria [124], and most centers have abandoned its use for this purpose.

The benefits of dobutamine and norepinephrine for patients with AKI reside in their ability to increase cardiac output, leading to an increase in renal blood flow [125]. Vasopressin increases systemic vascular resistance by direct action on the vascular smooth muscle cells. Vasopressin has been shown to be especially effective in maintaining renal perfusion in patients with septic shock who were unresponsive to catecholamine therapy [126].

Several recent systematic and narrative reviews have summarized many different therapeutic targets and drugs that have been studied, for which trials are ongoing or which are planned for human trials [127, 128]. Potential therapeutic targets for AKI include, but are not limited to, antioxidants, anti-apoptotics, anti-inflammatories, increasing renal blood flow and oxygen delivery, renal tissue repair (i.e., stem cells), and more conservative therapies such as hyperglycemia avoidance. Only a few are described herein. Some pharmacologic agents, such as calcium channel-blockers and *N*-acetyl cysteine, have been studied quite extensively in adults but have shown no substantial benefit on mortality or kidney outcomes [129, 130]. The selective dopamine A-1 antagonist fenoldopam may improve urine output in children undergoing cardiopulmonary bypass surgery [131]. Some studies suggest that nesiritide (a human natriuretic peptide) may have favorable renal hemodynamic effects and increase urine output after cardiac surgery [132]. However, clinical trials are lacking in children for most of these medications. Several studies in neonates with perinatal asphyxia have suggested that a single dose of theophyilline (an adenosine receptor antagonist) early after birth resulted in improved renal function and urine output [133]. There is also emerging, but tenuous and conflicting, evidence that adenosine receptor antagonists may prevent or reduce severity of AKI in children undergoing cardiac surgery [134, 135]. A recent meta-analysis on the use of pharmacological therapies for AKI in children undergoing cardiac surgery showed that the use of intravenous acetaminophen and the use of dexmedetomidine (an alpha-2 adrenergic receptor antagonist which many enhance intrarenal hemodynamics, prevent tachyarrhythmias and have preconditioning effects) may be beneficial to reduce postoperative AKI incidence [127, 136]. However, much more research is needed. Hopefully, with improved diagnostic assessment and increased ability to identify patients at highest risk for AKI (and thus, most likely to benefit from therapies), future research will identify pharmacological therapies which improve kidney outcomes and mortality in children with AKI.

Kidney Replacement Therapy

A substantial amount of literature has demonstrated that acute KRT for AKI may be provided safely to children of all ages. The biggest decisions reside in what modality of KRT to use and

Table 6 Advantages and disadvantages of different acute kidney replacement therapy modalities

Modality	Advantages	Disadvantages
Intermittent hemodialysis	Short treatment times Accurate ultrafiltration	Vascular access necessary Hemodynamic instability Heparin anticoagulation
Peritoneal dialysis	No need for vascular access Minimal equipment needs Minimal training needs Feasible in small infants Continuous treatment	Less efficient than hemodialysis or continuous renal replacement therapy Variable ultrafiltration dependent on blood pressure
Continuous renal replacement therapy	Accurate ultrafiltration that can be altered to account for changes in intake/patient blood pressure Smaller circuit volumes Citrate anticoagulation	Vascular access necessary

when to initiate it. No studies comparing dialysis modality and dose have been performed in children. It is therefore important to have an understanding of the use of all KRT modalities available in children. This section will focus mainly on technical aspects of continuous kidney replacement therapy (CKRT), since intermittent hemodialysis (IHD) and peritoneal dialysis (PD)) technical aspects are covered in chapters related to maintenance dialysis provision for children with end-stage kidney disease.

When fluid or electrolyte abnormalities are severe, KRT becomes the main treatment of choice for AKI. Traditional indications for KRT in AKI are hyperkalemia, severe hyperphosphatemia (especially if accompanied by hypocalcemia), severe metabolic acidosis or fluid overload, and symptoms of uremia. Non-kidney indications include prevention or treatment of tumor lysis syndrome to avoid uric acid or calcium-phosphate nephropathies, removal of toxins (ingestions or inborn errors of metabolism). While little has changed in terms of acute indications, the goal of prevention or early treatment of fluid overload using KRT has become more prevalent [38]. Acute KRT can be provided as IHD, PD, or CKRT. There are advantages and disadvantages to each of these modalities.

Modality Choice

Several factors, including dialysis indication and factors related to the patient's clinical status, determine the optimal KRT modality [137]. In general, factors determining optimal modality include patient size, hemodynamic stability, and institutional expertise. Table 6 outlines various advantages and disadvantages of the different acute KRT modalities. PD and CKRT are better suited for patients with hemodynamic instability, since daily total ultrafiltration goals can be achieved over a 24-h period instead of a 3–4 h IHD treatment. In patients with disrupted or severely scarred peritoneal membrane, PD may not be possible. Acute drug intoxications and hyperammonemia secondary to inborn errors of metabolism are most reliably treated with IHD since rapid drug removal is important to prevent morbidity and IHD is the most efficient KRT modality. However, several studies have shown that CKRT performed using very high solute clearance rates can also be effective for acute removal of ammonia and some drugs [138]. CKRT can be very effective for removal of some protein-bound drugs if albumin is added to dialysis fluid [139]. Sustained low-efficiency daily dialysis (SLEDD, often referred to as SLED for sustained low-efficiency dialysis) refers to using HD machines to administer HD over longer periods (e.g., 6–12 h), and is used in many centers with similar indications to the use of CKRT (e.g., hemodynamically unstable patients) [140]. Although duration and prescription of SLEDD may vary by patient needs and center, in general, dialysis fluid flow rates (and in older children, sometimes blood flow rate) are slower than in standard IHD (e.g., dialysis fluid rate of 100 ml/min instead of

500 ml/min). Recently, a somewhat interchangeable nomenclature for SLED was proposed: prolonged intermittent renal replacement therapy (PIRRT) [141]. This term may better reflect the flexibility of this modality, whereby blood flow, dialysis fluid rate, and duration and frequency of therapy can be modified according to the patient needs. Finally, the particular center's expertise and nursing support availability should play a major role in determining the optimal KRT modality.

Intermittent Hemodialysis

IHD is only discussed briefly here, as most details on materials, procedures, and prescription are discussed in a dedicated chapter. Vascular access issues are similar to what is discussed below in the section on CKRT. Acute IHD can be performed using similar machinery and dialysis solutions as in chronic HD, which means the need for a portable reverse osmosis device, purified water, and nurses specialized in performing HD. In hemodynamically stable patients with primary renal disease (e.g., acute glomerulonephritis, hemolytic-uremic syndrome), or in patients with inborn errors of metabolism or intoxications, IHD may be preferred because very efficient small solute clearance can be obtained within a short period and these patients will generally tolerate the procedure well. In patients with severe uremia, who are being treated with IHD for the first time, a relatively low clearance (aiming at a urea reduction ratio ≈ 30%) should be prescribed, in order to avoid the dialysis disequilibrium syndrome. If blood urea nitrogen is very high, intravenous mannitol or sodium profiling during dialysis may be helpful to avoid this complication. Heparin anticoagulation is generally used in IHD, which may complicate the clinical picture for patients with a coagulopathy. Heparin-free IHD can be achieved by performing frequent (approximately every 30 min) flushes with normal saline to the hemodialysis circuit. Hemodynamically unstable patients will often not tolerate a session of IHD, and, importantly, very tight fluid control will be necessary in between dialysis sessions, which may impair ability to provide adequate amounts of nutrition. In these patients, continuous modalities are preferable.

Peritoneal Dialysis

Acute peritoneal dialysis is a continuous dialytic therapy which requires much less technical expertise, expense, and equipment compared to IHD and CKRT. PD catheters can be placed quickly and easily. In centers with expertise, a non-tunneled PD catheter can be placed percutaneously at the bedside [142]), but these may have a high tendency to leak when inserted in centers with less experience in this procedure. Placing catheters surgically is preferable, similar to chronic PD catheter placement, and may avoid problems with peritoneal leak and resultant risk of infection [143]. Perioperative prophylactic intravenous antibiotics (e.g., cefazolin 15–20 mg/kg) are advisable. Flushing the PD catheter with dialysis solution and heparin after PD catheter insertion, until the effluent is clear, may reduce the risk of catheter blockage and malfunction and also allows for an early evaluation of catheter function. Several centers practice partial omentectomy when inserting acute PD catheters surgically, in order to minimize post-insertion catheter malfunction.

A recent trend toward providing PD therapy earlier in the post-cardiopulmonary bypass has been reported [144]. Improved survival with early PD initiation may result from prevention of fluid overload and potentially from abdominal decompression. Some authors suggest that improved survival with early post-cardiac surgery PD initiation may result from increased clearance of CPB-induced pro-inflammatory cytokines [145]), although further study is required to support this hypothesis. A study in infants undergoing cardiac surgery comparing patients who had intraoperative PD catheter placement (i.e., "prophylactic" PD) versus infants who did not showed that achievement of negative fluid balance and of extubation occurred more quickly in the intervention group [146]. A single center randomized controlled trial showed superior fluid removal with PD compared to standard dose diuretics [147]. The benefits of prophylactic PD catheter insertion on postoperative outcomes remains controversial [148, 149], but several centers perform this practice in high risk surgeries to aid in postoperative fluid management. Of note, for patients with some primary kidney diseases (e.g., glomerular diseases, hemolytic uremic syndrome) that do not require a critical care setting but who may be expected to require KRT for at least several days, PD may be preferred and should always be considered, because it is well tolerated and allows vessel preservation.

Standard PD equipment (including cyclers, or manual setups and solutions) can be used to perform dwells. Initial dwell volumes should be limited to 10 ml/kg of patient body weight in order to minimize intra-abdominal pressure, especially in patients with severe pulmonary dysfunction, and potential for fluid leakage along the catheter tunnel. Heparin is typically instilled in the dialysis fluid to prevent fibrin formation, for at least 48–72 h. Intra-dialysis fluid heparin should be continued for as long as fibrin is present in the dialysis effluent. Some centers also instill cefazolin in the dialysis solution for 48–72 h to help prevent infection. In patients receiving antibiotics, the use of antifungals should be considered, as is the practice for patients receiving chronic PD. If the patient's clinical status is stable, allowing 1–2 days for healing, prior to PD catheter use, may be helpful to prevent leakage; however, this has never been formally studied. In most patients in the acute setting, PD needs to be initiated very quickly.

Physiologic dialysis solutions should be used, and typically, a lower dextrose concentration solution is used initially (e.g., 1.36% Physioneal solution or 1.5% Dianeal solution); the resulting ultrafiltration can be evaluated after a few dwelling cycles and eventually, if required, the dextrose concentration can be increased. Fill volumes for dwells can be increased progressively, but slowly after several days, if there is no PD catheter site leak and if the PD catheter insertion was uncomplicated (particularly for tunneled catheters). In the acute setting, hourly cycles (with approximately 45 min of total dwell time) may be used and PD may be performed for 24 h/day. The dextrose concentration of the dialysis fluid and/or the cycle duration (as low as 15–20 min dwell time if needed) can also be manipulated to achieve the desired solute and/or fluid removal. PD delivers less efficient solute removal than IHD or CKRT and fluid removal (ultrafiltration) can be unpredictable; however, its relative simplicity allows for KRT provision in settings lacking pediatric dialysis specific support and personnel. Complications of acute PD include peritonitis, leakage around the tunnel or poor catheter function (i.e., blockage or inability to drain due to several reasons, similar to chronic PD complications). Moreover, especially relevant to critically ill patients, hyperglycemia may occur due to dextrose-containing dialysis solutions, and protein losses will occur, mandating increased protein intake to avoid protein-malnutrition. Hypothermia may also be a complication if dialysis solutions are not warmed.

Although not discussed in detail here, it is worth mentioning the possibility of performing what has been referred to as continuous flow peritoneal dialysis (or CFPD)[150, 151]. This therapy requires insertion of two PD catheters (although the use of one PD catheter and one smaller peritoneal drainage tube has been described); alternatively, the use of a double lumen PD catheter has also been described. The abdomen is initially filled with a predetermined volume of dialysis solution (e.g., 10 ml/kg) via the "inflow" PD catheter, after which "continuous flow" of dialysis solution (into the abdomen via the inflow catheter and out of the abdomen via the outflow catheter) at relatively high flow rates. Different flow rates are described in the referenced articles, but can range, for example, from 40 ml/h to several hundred or 1000 ml/h, depending on whether high solute clearance is needed versus steady, continuous clearance. The "outflow" rate can be increased, relative to the inflow fluid rate, to achieve the desired net patient ultrafiltration. Different methods for achieving the desired dialysis fluid inflow and outflow rates have been described, including using CKRT machines; intravenous pump machines; using gravity for the fluid outflow collection bag (which requires very careful monitoring). In addition, it is essential to regularly empty the abdomen, as fluid absorption via the peritoneal membrane is not predictable (e.g., the patient may have 200 ml/h flowing continuously through the abdomen, which is otherwise empty due to absorption). Moreover, PD catheter obstruction can be detrimental to the patient and must be monitored very closely. Severe electrolyte imbalances may occur, thus these patients should be monitored as closely as monitoring is performed for patients receiving CKRT. The main advantages of CFPD are that both solute clearance and ultrafiltration rates achievable are much higher than what is feasible with traditional, single-catheter PD. This therapy thus offers an alternative to CKRT when CKRT equipment is unavailable. Another advantage is for very small infants, in whom both CKRT and larger peritoneal fluid volumes may not be tolerated or feasible.

Continuous Kidney Replacement Therapy

Various CKRT aspects, including dose, dialysis/replacement fluid composition, and anti-coagulation methods, have been studied in recent years. The term CKRT generally refers to one of three treatment modalities: continuous venovenous hemodialysis (CVVHD), continuous venovenous hemofiltration (CVVH), or continuous venovenous hemodiafiltration (CVVHDF). In each of these CKRT modalities, dialysis or replacement fluid is generally not from a water source, like in IHD; rather, solution bags are hung on the CKRT machine and delivered to achieve solute clearance. In CVVHD, like in IHD, a physiologic dialysis solution is run countercurrent to blood flow through the hemofilter. The mode of solute removal is by diffusion and small solutes are removed effectively. The CVVH modality uses a *replacement* solution, which is similar in composition to dialysis fluid, but is infused into the CKRT circuit (and thus into the bloodstream of the patient) either pre-hemofilter (pre-dilution) or post-hemofilter (post-dilution). The same volume of fluid is removed by ultrafiltration simultaneously through the hemofilter in order to achieve solute removal by convection (solute drag). Small solute removal efficiency with CVVH by convection is similar to small solute clearance with CVVHD by diffusion, but larger molecules with molecular weights greater than 1000–10,000 Daltons are removed more efficiently with CVVH. In CVVHDF, both dialysis and replacement solutions are used to achieve solute removal. In all forms of CKRT, additional fluid volumes to the dialysis and/or replacement volumes are removed by ultrafiltration, with the goal of controlling fluid balance according to patients' needs.

Vascular Access

A well-functioning vascular access is essential to the success of IHD or CKRT. The most common sites for acute catheter placement are the internal jugular, subclavian, and femoral veins. Avoiding the subclavian vein is preferable to prevent subclavian vein stenosis in patients who may need permanent vascular access in the ipsilateral upper extremity. The femoral vein provides the advantage of relatively easy and prompt access. However, with the availability of skilled surgeons or intensivists and ultrasound guidance, internal jugular venous placement is also attainable safely. Patient characteristics may also influence the choice of catheter placement. For example, in patients with severe ascites or with a suspected need for a future kidney transplant, internal jugular placement may be preferable, whereas in patients receiving high-frequency oscillatory ventilation, femoral placement will be technically easier and reduce the risk of pneumothorax associated with internal jugular venous access.

A study of adult patients reported increased recirculation and worse performance in catheters placed in the femoral vein versus subclavian or jugular veins [152], and pediatric data suggest that internal jugular access is associated with longer CKRT circuit survival than femoral or subclavian access, independent of anticoagulation method [153]. Catheter size should also be matched to patient size [154]. However, smaller catheters (five French double lumen catheters) are associated with very poor circuit survival, due to clotting and poor blood flow and should be avoided if possible. Of note, with the recent availability of CKRT machines designed for very small infants, the need for traditionally high blood flows may not be needed and thus, vascular access should also be adapted to the technology being used. In these novel CKRT machines developed for use in infants ("miniaturized circuits," described below) use of much smaller

Table 7 Examples of vascular access catheter sizes by size of the patient for performing acute CKRT. (This list is simply an example of catheter selection (without commercial product names), specifically designated by patient size. It is important for each center to be aware of the different vascular access catheters available to them)

	Weight	Catheter
Internal jugular (neck) catheters	<5 kg	8Fr (sometimes 6.5Fr)
	5 kg to <20 kg	10Fr
	20 kg to <35 kg	12Fr
	>35 kg	13.5 or 15.5 Fr
Femoral catheters	<5 kg	6.5Fr (10 cm)
	5 to <20 kg	8Fr (12.5 cm) 10Fr (12 cm) if close to 20 kg
	20 to <40 kg	10Fr (15 cm)
	>40 kg	11.5Fr (13.5 cm or 16 cm)

catheters (including five French double lumen catheters) is feasible [155]. Maintaining access patency between CKRT sessions using heparin or citrate catheter locks is essential to prevent access clotting. Table 7 provides some examples of catheter choice by patient size; however, different centers will have different catheter choices available.

Machines and Hemofilters

Modern CKRT machines are generally user-friendly and consist of computer modules from which physicians may choose the CKRT modality. Accurate ultrafiltration with volumetric/gravimetric control incorporated into machines and disposable lines, and circuits and dialyzers, sized for the pediatric weight spectrum have made CKRT safer in children. Accurate UF and blood flow rates are crucial for pediatric KRT since the extracorporeal circuit volume can comprise more than 15% of a small pediatric patients' total blood volume and small UF inaccuracies may represent a large percentage of a small pediatric patient's total body water. Most of these machines also contain blood air leak detectors, a blood pump, dialysis fluid, and replacement fluid pumps. CKRT machines may also be connected to other extracorporeal machines simultaneously, including ECMO circuits and plasmapheresis devices. This aspect of CKRT will not be discussed herein but is described in the literature [156, 157].

Hemofilters are available in different sizes, as measured by internal membrane surface area, from as low as approximately 0.2 m^2 to over 1 m^2, and range from 60 to over 150 ml of blood volume. Some machines have specific hemofilters associated with them, whereas others are more versatile and can accommodate different hemofilters. Moreover, not all hemofilters are available in all countries. It is thus important to be aware of what hemofilters are available and to have as wide a size selection as possible to fit the range of weights (<3 kg to 100 kg) of patients being treated. Thus, hemofilters are chosen based on the type of machine being used and the size of the patient. Despite the smaller sizes of some hemofilters, delivery of CKRT to infants or small patients entails a significant portion of their blood volume to be pumped through the extracorporeal circuit. Therefore, extracorporeal circuit volumes that comprise more than 10–15% of patient blood volume (or even less, if the patient is hemodynamically unstable) should be primed with blood to prevent hypotension and anemia. When the extracorporeal circuit volume is close to 10% of the patient's blood volume, if the patient is severely anemic or is hemodynamically unstable, priming the circuit with blood or with 5% albumin may also be needed. CKRT hemofilters are made of polysulfone or of acrylonitrile (such as the AN69). AN69 membranes are associated with risk for bradykinin release syndrome (which may cause a range of mild to profound hypotension). Bradykinin release syndrome appears to be worse when acidic blood (packed red blood cells in the blood prime) comes into contact with the AN69 hemofilter. Several methods are described to mitigate this reaction, including administration of bicarbonate together with the blood prime, administration of intravenous calcium gluconate when initiating CKRT (to prevent hypocalcemia) as well as performing "pre-dialysis" for 5–10 min of the blood prime solution, before connecting the patient to the CKRT machine [158]. In the latter method, the blood is circulated through the machine against dialysis fluid in order to normalize pH, calcium, and potassium of the blood. In some countries, protein-coated AN69 membranes are available, which greatly reduces the incidence of bradykinin release syndrome. Alternatively, during CKRT inception, the crystalloid priming can be discarded and not reinfused to the patient, while a blood transfusion can be delivered to the patient through another vascular access in order to balance the amount of patient blood that is required to fill the circuit.

Recently, newer machines have been specifically designed or modified for use in neonates, to minimize extracorporeal volume (as low as <10 ml) during CKRT treatment (and to allow for smaller vascular access requirements and blood flows, as described above) [159–163]. These are only briefly mentioned here, as they are described in a dedicated chapter. Only one of these devices was developed specifically for neonates and is currently available and approved for widespread use in some countries: the Cardio-Renal Pediatric Dialysis Emergency Machine (CARPEDIEM) machine (priming volumes as low as 30 ml). Published experience appears encouraging, though more research is needed to determine the extent to which the goals of using a smaller machine (reducing need for transfusions and other complications of high extracorporeal volume; absolute need for PD in very small infants) are being widely achieved [155, 161, 162]. Another device, specifically developed for neonatal CKRT, is the Newcastle Infant Dialysis and Ultrafiltration System (NIDUS; extracorporeal volume reportedly as low as <10 ml); however, this device is currently still undergoing initial trials and evaluation. Another device, the Aquadex machine (originally conceived as a small device for slow continuous ultrafiltration in adult patients), has been described to be successfully used for delivering CKRT in children below 10 kg, by modifying the original machine technology and application [163].

Dialysis and Replacement Fluid Solutions

In most centers, the same solutions are used for dialysis fluid (in CVVHD) and for replacement fluid (CVVH). Several different types of solutions are shown in Table 8; there are many other types of solutions available and Table 8 simply provides an example of the different contents that dialysis and replacement solutions may have. The majority of centers will utilize commercially available physiologic solutions which contain a buffer, and varying amounts of electrolytes (sodium, potassium, magnesium, calcium, phosphorous) and glucose. Previously, most CKRT solutions used lactate as a buffer. However, more recent solutions use bicarbonate as the primary buffer (with small concentrations of lactate). Evidence from adult patients treated with CKRT suggests that lactate-based solutions may cause rising patient lactate level which may lead to inappropriate concern for tissue ischemia, or conversely, lack of investigation for tissue ischemia if the issue is assumed to be caused by the dialysis solution [164]. Bicarbonate buffered solutions can be made by hospital pharmacies, but are also now available from industry sources. Some centers use pharmacy-prepared solutions; however, this may be associated with safety implications due to compounding errors [165]. Thus, a solution composition validation program should exist in centers that opt to use if pharmacy-made solutions for CKRT. Commercially available CKRT solutions may or may not contain calcium. When performing CKRT using citrate-based anticoagulation (described below), non-calcium containing solutions are generally used. However, if using heparin-based anticoagulation, use of calcium-free solutions may lead to profound hypocalcemia. Within 24–48 h of CKRT initiation, it is extremely common to develop hypokalemia and/or hypophosphatemia. Both potassium and phosphate (in the form of sodium or potassium phosphate) may be added to the CKRT solutions. Some commercially available solutions already contain some potassium or phosphate. There is concern about precipitation of phosphate-calcium crystals with the solution bags, particularly if using calcium-containing solutions. In fact, several in vitro and some

Table 8 Examples (non-exhaustive) of some commercially available CKRT dialysis and/or replacement fluid solutions, to demonstrate the different potential solutions contents. (Many other solutions exist from different companies. However, as shown, typically calcium, potassium, and also phosphate content will vary significantly. Also (not very evident in this table), the types of buffers used may vary significantly as well. Items of interest and of specific clinical significance to patients and CKRT delivery are bolded)

human adult studies have shown that precipitation at various CKRT solution concentrations is not common [166–168]. Nevertheless, it is wise to limit maximal solution phosphate concentrations to 1.5–2 mmol/l. For patients with severe hypo- or hypernatremia, in whom rapid change in patient sodium concentration could be detrimental, either sodium chloride or sterile water may be added to the dialysis and/or replacement solution bags to tailor the delivered sodium concentration. Great care must be taken to ensure a lack of errors when doing this. When performing CVVHD (and not CVVH), the dialysis solution can be modified to create a 4 or 5% albumin dialysis solution (by adding 25% albumin to the dialysis solution bags), in order to perform "single-pass albumin dialysis." This type of CKRT may be useful in specific conditions (e.g., Wilson's disease to remove copper; to remove some protein-bound drugs in intoxications; in some cases with severe liver disease) [139, 169].

Blood Flow, Solute Clearance, and Ultrafiltration

With CKRT, as opposed to IHD, the blood flow rate has more substantial impact on circuit patency (lower blood flows being associated with a higher risk of circuit clotting), than on solute clearance. Solute clearance in CKRT is largely a function of dialysis and/or replacement fluid flow rates and of the time spent on treatment. Blood flow rate is determined by patient size, hemofilter size, and vascular access. Blood flow rates can range from 2 to 10 ml/kg/min. In general, for most machines, blood flow rates lower than 30–50 ml/min will be associated with significant risk of clotting of the circuit or of the vascular access. As a general rule of thumb, for patients under 10 kg, rates of 30–50 ml/min are used, and in the largest children, rates of 100–200 ml/min are used. Because of the need to maintain circuit patency with minimum blood flows, CKRT blood flow rates are high in neonates, relative to body size (e.g., 50 ml/min in a 5 kg baby is 10 ml/min/kg); thus, when using citrate anticoagulation (citrate rate prescription is based on blood flow rate, described below), citrate load may be relatively high for neonates.

Regarding treatment prescription, or "dose" of solute clearance, no prospective study in the pediatric setting has addressed its impact on patient mortality or other outcomes [170]. Again, solute clearance "dose" is mainly determined by dialysis fluid rate (in CVVHD), replacement fluid rate (in CVVH) or the addition of dialysis plus replacement fluid rate (in CVVHDF). A standard recommended total solute clearance dose is approximately 2 l/h/1.73 m^2; in patients weighing more than 40 kg, this corresponds approximately to an effluent flow rate of 25–35 ml/kg/h, which is the currently recommended prescription in adult patients [1]. At this level of clearance, the majority of metabolic disturbances of AKI will be managed. However, when prescribing CKRT, the dose should be tailored to the patients' clinical needs. For example, in patients with life-threatening hyperkalemia or hyperammonemia, much higher solute clearance can and should be prescribed (e.g., 4 to 8 l/h/1.73 m^2). However, if prescribing very high clearance rates, it is important to be aware of the negative consequences, including clearance of amino acids (i.e., nutrition), medications, other electrolytes (e.g., magnesium) as well as the possibility of dialysis disequilibrium syndrome in patients with very high urea and/or chronic or acute on chronic kidney disease. Citrate anticoagulation will also be more complicated when using very high solute clearance rates, because of clearance of citrate, requiring closer monitoring (monitoring described below).

Ultrafiltration (net fluid removal from the machine, sometimes referred to as netUF) is a crucial goal of CKRT. NetUF should be approached in such a way that fluid removal goals are achieved, while maintaining patient safety and avoiding aggressive ultrafiltration. The net daily negative patient balance (and thus, hourly net negative patient balance) should be discussed and agreed upon between nephrology and ICU teams and should take into account the netUF rate along with patient residual diuresis and all current and expected fluid infusions to the patient in the next 24 h. Moreover, when determining the desired patient net negative balance goals and ultrafiltration, the presence of other fluid outputs (e.g., urine output; nasogastric tube; stool; chest tube) should be considered, to achieve safe fluid removal targets. There is no absolute safe maximum negative hourly net patient fluid removal rate, but rather, empiric guidelines that may be used. Ultimately, decisions on hourly negative balance will be dictated by the patient's hemodynamic stability together with the urgency of requirement for fluid removal. One rule of thumb to avoid overly aggressive fluid removal in CKRT is to avoid targeting a daily net negative balance (in liters) of greater than 3–5% of body weight, with a lower target in patients who are more hemodynamically unstable. Another rule of thumb is to avoid targeting a net hourly negative balance of greater than 1–2 ml/kg/h. The fundamental difference between netUF (the fluid removed from the machine) and fluid balance (the ultimate difference between fluids infused and fluids removed from the patient) should always be kept in mind. Moreover, it may sometimes be necessary to increase vasopressor support in order to achieve net fluid removal goals. These suggestions are but starting points for approaching fluid removal and should be reassessed frequently and whenever the patient's clinical status changes significantly.

Anticoagulation

Anticoagulation of the CKRT circuit is essential to provide the therapy in children. Heparin and citrate are the two most common forms of anticoagulation. Heparin anticoagulation is achieved by continuous infusion of heparin to the CKRT machine circuit, pre-hemofilter and monitoring partial thromboplastin time (PTT), and/or activated clotting time (targeting systemic PTT ~1.5 times normal and/or activated clotting time of 180–220 s). In certain situations (e.g., postoperative, known bleeding risk, or when using higher blood flows), anticoagulation targets may be lower. The side effects of heparin include systemic anticoagulation and the rare occurrence of induction of heparin induced thrombocytopenia. Patients who are deemed to be at very high bleeding risk should not receive heparin. Increasingly, regional (restricted to the CKRT circuit) citrate anticoagulation is being used by many centers, instead of heparin. Citrate anticoagulation is performed by continuous infusion of citrate solution at the access ("arterial") side of the circuit running from the patient to the CKRT machine. Anticoagulation is achieved by binding to and decreasing ionized calcium in the blood, which is required for the activation of the clotting cascade. Once returned into the bloodstream the calcium-citrate complexes are processed in the Krebs cycle (mainly muscles, liver, and generally all body tissues), calcium is released into the blood, and citrate is metabolized into bicarbonate and ATP. Calcium is infused into a separate systemic central venous line or at the return ("venous") portion of the dialysis catheter, to maintain physiologic ionized calcium in the patient replace calcium losses (part of the complexes citrate-calcium are removed through the filter). The potential complications of regional citrate anticoagulation include metabolic alkalosis (especially if used in combination with bicarbonate buffered CKRT replacement/dialysis solutions) and citrate lock. Citrate lock occurs when the delivery of citric acid and citrate exceeds the patient's hepatic clearance and the clearance of citrate through the hemofilter. As a result, citrate concentrations increase in the patient's blood and bind calcium. Citrate lock is identified by decreasing serum ionized calcium in the presence of rising total calcium (a rule of thumb is the ratio of ionized calcium to total calcium in the patient >2.5–2.8 being indicative of citrate accumulation). A metabolic acidosis may also occur with citrate lock. The treatment for citrate lock (which is essentially citrate accumulation) is to either reduce citrate delivery or increase its clearance (or both). Citrate may be discontinued for 1–4 h and then restarted at a lower citrate delivery rate. Temporarily increasing clearance (increasing the dialysis fluid or replacement fluid rate) may also help reduce systemic citrate concentrations, though close attention to electrolyte abnormalities and other dialytic losses (medications, nutrition) should be considered. Reducing the blood flow may also help to decrease citrate delivery, as citrate delivery rate is dependent on blood flow. When alkalosis is present (due to metabolism of citrate by a functioning liver), either 0.9% normal saline may be delivered as a replacement solution via the CKRT machine or, if available, a lower bicarbonate concentration CKRT solution may be used for dialysis and/or replacement solution. Pediatric studies have reported practical and safe citrate anticoagulation protocols [171–173]. Of note, when there is very severe liver disease or significant systemic hypotension with muscle tissue hypoperfusion (e.g., septic shock), the risk for citrate accumulation increased significantly. Moreover, in small babies, citrate accumulation is quite common, because the blood flows required to maintain circuit patency are relatively high for these patients' body sizes; thus, citrate delivery is also relatively high.

Complications

In addition to the CKRT complications noted above, another complication of CKRT is hypothermia, particularly in infants. This can be avoided by the use of heat lamps, dialysis fluid warming and blood tube warmers. Electrolyte disturbances can occur, particularly hypophosphatemia, hypomagnesemia, and hypokalemia, due to dialytic clearance and can be avoided by frequent electrolyte monitoring and appropriate adjustment of dialysis and/or replacement solution composition. Excessive ultrafiltration is a problem that may frequently occur, but can avoided by careful patient monitoring with hourly fluid balance, and frequent reassessment of the day's goals by the pediatric nephrologist. Incorrect dosing of drugs may also occur. In children receiving prolonged citrate anticoagulation, due to chronic calcium binding in the blood, the potential for increased risk of fractures and bone disease has been described [174].

Nutrition

Adequate nutrition in critically ill children with AKI is a component of their treatment, particularly critically ill children, who are at increased risk of developing protein-energy malnutrition. Critically ill patients with severe AKI are considered highly catabolic and the presence of KRT contributes to nutritional losses, especially amino acids and water-soluble vitamins. Similar to what has been found in adults, amino acid losses by standard clearance CKRT can be anywhere from 10 to 20% of the amount provided in the parenteral nutrition, which is associated with the development of negative nitrogen balance [175, 176]. Given the age-associated baseline elevated protein needs of children and the presence of abnormal amino acid synthesis and increased protein catabolism in critical illness and AKI, daily protein intake should be in the order of at least 3 g/kg/day in children treated with CKRT and should be adjusted if higher solute clearance doses are provided.

Drug Dosing

Drug dosing must often be altered for patients with AKI, not only for avoiding kidney injury, but to avoid toxic accumulation of drugs and their metabolites which are excreted by the kidney. When glomerular filtration rate is estimated to be less than 50% of normal, most drugs excreted by the kidney will require modifications in scheduled dosing. For patients receiving CKRT, drug dosing can be quite challenging. However, understanding the size, volume of distribution, and protein binding of the drug (for each of which, if high, leads to less clearance through the hemofilter) can estimate appropriate drug dosing. Moreover, for some drugs, there may be *adsorption* of the drug to the hemofilter, particularly when using convective clearance (i.e., CVVH). This should be considered if a certain drug a patient is receiving is thought to be critical to their treatment. Several excellent recent review articles discuss how to specifically dose different drugs during CKRT or with AKI, based on these biochemical properties [177, 178]; however, in vivo validation of these concepts is minimal and an area of much-needed research [179].

AKI Follow-Up

As discussed above, there is increasing evidence of long-term negative effects of AKI, including CKD or hypertension. The KDIGO guidelines currently recommend that patients who develop AKI should be evaluated at 3 months after discharge to evaluate for recovery from AKI and/or the development of CKD [1]. No studies have specifically determined and/or evaluated the adequate time or frequency for follow-up after an episode of AKI in children. Moreover, different healthcare contexts will be faced with varying resource issues in being able to follow-up all patients who developed AKI. Some resources are available to help guide how to approach long-term follow-up of AKI in children [180–182].

One approach is described in a publication describing an AKI survivor clinic [182]. Children with Stage 2 AKI or worse are identified by the EHR, triggering referral. A clinic staff reviews EHR-triggered referrals and ensures 3, 6, and 12 month follow-up visits for CKD and hypertension screening and treatment, patient and healthcare provider education, and mitigation of future AKI risks. Such a program requires institutional support, multi-team coordination and an EHR to perform AKI "alerts." Another proposed approach [181] is to risk-stratify/select AKI patients who would benefit the most from follow-up; this selection is not solely based on AKI severity, but also on other factors such as non-recovery from AKI before discharge, location of event (intensive care unit *vs.* hospital ward), urinary biomarker data, and/or AKI recurrence.

Another approach is described below. First, when a child who developed AKI during hospitalization is being prepared for discharge, at the very least, an assessment of (a) complete recovery or non-recovery from the AKI episode (i.e., measure SCr) and blood pressure and (b) overall risk for long-term complications of AKI (i.e., risk factors presented in Fig. 1a) should be made. Patients with Stage 2 AKI or worse are more likely to have long-term complications [183]; those without recovery at discharge should also be considered for follow-up. Based on the level of risk and severity of abnormalities, if a dedicated AKI follow-up clinic or outpatient nephrology resources are not available, then the healthcare provider best suited to perform post-AKI follow-up should be identified before discharge, informed about the AKI episode and provided with instructions on what evaluations to perform at follow-up and criteria for referring to nephrology care. An effort should be made to ensure that patients with clear risks for long-term kidney disease, baseline kidney disease, or significant kidney dysfunction or hypertension before discharge are followed by a nephrologist after discharge. The family should also be educated and informed that an AKI episode occurred, in order to promote prevention of future AKI episodes. Families that are aware of the AKI episode and of the concept of kidney protection are more likely to inform future healthcare providers and potentially more likely to encourage them to avoid nephrotoxic medications. As described in the description of the AKI survivor clinic above [182], at the first follow-up visit, the main goals are determining if the underlying AKI and AKI cause has resolved, educating families (e.g., avoiding nephrotoxins; informing primary physicians of the AKI), screening for kidney health risk factors (e.g., nephrotoxins, obesity), promoting health lifestyle habits and evaluating estimated GFR, proteinuria, and blood pressure. Previously healthy children with no risk factors outlined above and complete AKI resolution before discharge should undergo at least urine (for proteinuria) and blood pressure examination at the first follow-up visit. If all parameters are normal and the patient is felt to be low-risk, follow-up kidney health assessment approximately 1 year later, with reassessment every 1 or 2 years, is likely reasonable.

The Acute Dialysis Quality Initiative 22nd conference consensus document described above (for primary and secondary prevention of AKI) also provides guidance to long-term AKI follow-up, though these recommendations were developed for adults [3]. A pediatric-specific approach will likely be developed in the future. They provide a framework for what post-discharge follow-up visits should include in patients who suffered an AKI episode. This framework is described by the acronym "K.A.M.P.S" and is very concordant with the AKI follow-up approaches described above: *Kidney Function:* estimated GFR; proteinuria/albuminuria assessment; other biomarkers or imaging as indicated (to which we add blood pressure assessment); *Advocacy:* patient and caregiver education; communication with care providers; *Medications*: medication reconciliation, review, and management; review and discuss risk benefits of potentially nephrotoxic medication and review medication potentially impacted by kidney function; *Pressure:* ensure patient understands blood pressure goals and targets; discuss fluid status, ideal weight, role of diuretics; *Sick Day Protocols:* educate patients on medications that need monitoring during acute illnesses (e.g., in some patients, holding ace-inhibitor treatment with significant dehydration episodes).

Conclusions

As shown in this chapter, AKI has been increasingly acknowledged internationally as a common and important problem, with potentially long-lasting negative impacts on kidney health and other outcomes. Many initiatives are underway to guide the care of AKI patients, with a major focus on awareness (by patients, healthcare providers, and healthcare systems) as well as on research to improve AKI diagnosis and healthcare delivery, with a goal of improving outcomes [184, 185].

Abstract

The excretion of endogenous and exogenous compounds is a fundamental aspect of renal function, which, by necessity, exposes the kidney to high concentrations of these substances and their metabolites. Some of these compounds are “toxic” to the kidney and substances capable of causing renal damage or injury are termed “nephrotoxins.” While naturally occurring nephrotoxins exist and environmental exposures can cause injury, the focus of this chapter is on the pharmaceutical agents used to treat medical disease and its sequelae. While specific, ubiquitously prescribed agents are discussed in detail, equal weight is placed on highlighting core nephrotoxin concepts, illustrating the most commonly seen nephrotoxicity phenotypes, and describing the mechanisms by which these compounds cause injury. This foundation creates the context for discussing approaches to avoid, minimize, and manage the impact of nephrotoxin exposure. Although targeted treatments for nephrotoxic acute kidney injury do not yet exist, broad multidisciplinary strategies are capable of predicting, preventing, and mitigating the impact of these medications. Furthermore, a thorough understanding of the core concepts underpinning nephrotoxicity will allow future development of disease-specific interventions.

Nephrotoxin · Nephrotoxic · Acute kidney injury · AKI · Prevention

Introduction

One of the most fundamental aspects of kidney function is the elimination of endogenous and exogenous compounds. Indeed, evaluation of excretory function is the cornerstone of assessing renal physiologic capacity. Excretion, by necessity, exposes the kidney to high concentrations of these substances; at high concentrations, these compounds and their metabolites can be toxic, causing injury or damage to the kidneys [1–4]. In 1965, Dr. George Schreiner described this “toxin nephropathy” as “any adverse functional or structural changes in the kidney due to the effect of a chemical or biological product that is inhaled, ingested, injected, or otherwise absorbed, or that yields toxic metabolites with an identifiable adverse effect to the kidneys [5, 6].” Since then, this “nephrotoxicity” has been variably referred to in the literature as “drug-associated acute renal failure” [7], “drug-associated or drug-induced acute kidney injury” [8], “drug-induced kidney disease” [9], or occasionally with disease-subtype-specific language such as “drug-induced ANCA-associated vasculitis” [10]. However, the concept of nephrotoxicity has evolved and now broadly refers to any adverse effect of a substance on kidney structure or function.

As a corollary, substances capable of causing such injury are now referred to as nephrotoxins.

Over the past two decades, nephrotoxins and nephrotoxicity have been widely studied and our understanding of mechanisms, epidemiology, and management has increased substantially. In this context, it is important to introduce several broad concepts. The first such concept is the manner in which the toxicity presents itself; recognizing toxicity phenotypes is central to our understanding of the agents themselves. In 2015, Mehta characterized nephrotoxicity as having four distinct phenotypes [9]. Specific mechanisms of injury are discussed later in the chapter; however, in terms of clinical presentation of disease, this is an informative construct. The most ubiquitous and widely accepted phenotype is that of acute kidney injury (AKI). In these situations, after receiving a nephrotoxin, a patient experiences a rise in serum creatinine consistent with injury and reduced excretory function; aminoglycosides are a classic example of the AKI phenotype [11]. A second phenotype that is common is crystalluria. These patients experience crystal formation in the urinary tubules or, less commonly, nephrolithiasis; acyclovir is a nephrotoxin which commonly presents as crystalluria and sulfa-based antibiotics can lead to stone formation [9, 12, 13]. A third phenotype is that of tubular dysfunction. Such patients present with preserved excretory function but have evidence of tubular mishandling of fluid and/or electrolytes; the Fanconi syndrome seen with ifosfamide and the diabetes insipidus associated with lithium therapy are classic examples of this phenomenon [14–17]. The fourth phenotype described is glomerular disease. While less common than the other three phenotypes, these patients may present with hematuria, proteinuria, or even a mixed nephritic/nephrotic picture. Examples include the nephrotic syndrome and podocyte dysfunction seen with sirolimus, the focal segmental glomerulosclerosis seen with pamidronate or adriamycin, and the anti-neutrophil cytoplasmic antibody (ANCA)-associated glomerulonephritis seen with d-penicillamine [18–20].

The second important concept is the temporal component of nephrotoxicity; renal injury generally occurs over three time horizons – acute, subacute, or chronic [9]. Acute nephrotoxicity characterizes injury, which occurs within approximately 1 week of exposure; the acute tubular necrosis (ATN) caused by amphotericin is a good example of acute nephrotoxicity [21]. Subacute nephrotoxicity, such as the acute interstitial nephritis (AIN) seen with nonsteroidal anti-inflammatory drug (NSAID) exposure, typically develops over weeks to months [22, 23]. Finally, chronic nephrotoxicity is commonly defined as renal disease seen after at least 3 months of exposure; the nephropathy seen with calcineurin inhibitor administration often becomes apparent months to years after solid organ transplantation [24]. Knowledge of the nephrotoxin time horizon for injury helps set expectations and guide monitoring strategies.

Third, it is important to consider the exposure-response relationship of a nephrotoxin as this may influence management and mitigation decisions. Certain medications or classes exhibit a dose-dependent effect [25], described as a “Type A” nephrotoxicity [9]. Drug toxicity in these cases is typically a function of the maximal concentration achieved or the overall exposure as described by the area under the concentration-time curve [25]. While drug discontinuation is the preferred intervention to limit further kidney damage, a decrease in the drug dose or rate of administration may be a suitable alternative option if the drug is required and no other therapies are available. Other medications or classes are associated with an idiosyncratic or unpredictable effect, known as “Type B” nephrotoxicity [9]. Kidney injury in these situations is dose-independent and, as a result, a dose reduction is unlikely to affect the potential for long-term kidney damage; discontinuation of the substance is typically necessary to avoid further injury.

A fourth consideration, specific to children, is the influence of developmental factors on the risk for toxicity. In neonates, the immaturity of tubular transporters in early life may act as a renal protective mechanism for drugs that increase their potential for injury via intracellular concentration (e.g., aminoglycosides) [26, 27]. On the other hand, neonates’ inability to maximally concentrate their urine may predispose to intravascular volume depletion which increases the nephrotoxic potential of medications that affect renal hemodynamics [27–30]. In infants, renal excretory function gradually increases from birth, reaching adult normative values at approximately 2 years of age

[31]. During this transition, accurate dosing can be challenging and the risk of nephrotoxicity may be increased, particularly with substances whose excretion is primarily renal in nature [32]. Other pharmacokinetic changes in the first 2 years of life, including the evolution of enzymatic function and changes to the proportion of total body water, can alter drug distribution, overall exposure, and toxicity risk [27].

Finally, it is important to highlight the concept of comprehensive "nephrotoxin burden." While many epidemiologic studies have investigated the association between a specific substance in a specific population (e.g., cisplatin in pediatric cancer patients or aminoglycosides in patients with cystic fibrosis) [33, 34], the overall nephrotoxic burden a patient is exposed to may have more clinical relevance than the impact of any single agent. This concept was first introduced by Merlin Thomas in 2000 when he coined the term, "triple whammy" [35], which referred to the combination of a diuretic, an NSAID, and an angiotensin-converting enzyme (ACE) inhibitor ubiquitously prescribed to patients with heart failure. He found that more than 50% of iatrogenic AKI in this population could be ascribed to one or more of these agents [6, 35]. The concept of nephrotoxic burden has been further refined by the Nephrotoxic Injury Negated by Just-in-time Action (NINJA) program [36–39]. This initiative defines a large nephrotoxic burden as receipt of three or more agents concomitantly or the administration of particularly injurious agents for a prolonged duration. Studies designed to identify patients exposed to a large nephrotoxin burden have proven quite successful at mitigating injury [36].

In summary, our conceptual understanding of nephrotoxins, the injury they cause, and optimal management strategies have grown tremendously. Although specific treatments for nephrotoxic injury are not currently available, approaches designed to increase awareness, identify high-risk patients, and prevent unnecessary exposure have helped to mitigate disease severity. This chapter will focus on nephrotoxic compounds, mechanisms of injury, and management strategies. Additionally, some specific, commonly used nephrotoxins will be described in detail. Given the continued developments in medicine, the globalization of society, as well as the changes in our environment, the risk for injury is not likely to decrease over time and a robust understanding of this topic will be of paramount importance for practitioners of pediatric nephrology.

Types of Nephrotoxins

The term nephrotoxin is generally used to refer to pharmaceuticals that are intentionally administered despite having a side effect profile that includes kidney injury. However, it is important to be aware of the numerous other substances capable of causing significant kidney harm which include both synthetic and naturally occurring toxins. Exposure to some of these various nephrotoxic substances may depend on geographical location, seasonality, and specific subpopulation.

Pharmaceuticals

Pharmaceuticals have been the subject of extensive research and inquiry as many drugs have a side effect profile containing the undesirable potential for kidney injury. These medications may be prescription or over-the-counter (OTC). Nonprescription medications, while widely available, are not without risk [6, 22, 40, 41]; indeed, The 2012 Kidney Disease Improving Global Outcomes (KDIGO) AKI guidelines underscore the importance of considering oral nephrotoxins such as NSAIDs, in addition to the more commonly considered intravenous medications, when performing risk stratification and prediction modeling [42]. Medications which have only recently become available likely warrant more deliberate reflection before drawing firm conclusions. Vascular endothelial growth factor (VEGF) inhibitors, for example, have mixed data with regard to renal injury; ultimately, their true nephrotoxic potential will be born out over time [43]. While it is challenging to produce an all-encompassing list of nephrotoxic pharmaceutical agents, an article by Perazella and the NINJA collaborative have attempted to do just

Table 1 Nephrotoxic medications and compounds by category or class

Pharmaceutical agents	Pharmaceutical agents (cont.)	Naturally occurring compounds
ACE inhibitors (category)	NSAIDs (category)	Aristolochic acid
Aminoglycosides (category)	Orlistat	Cape aloes
Analgesic combinations (category)	Pentostatin	Datura species
Anti-angiogenesis medications (category)	Phenacetin	Dichromate
Antivirals (category)	Platins (category)	Ephedra species
Amphotericin B	Polymixin B	Glycyrrhiza species
ARBs (category)	Selective COX-2 inhibitors (category)	Mefenamic acid
Bisphosphonates (category)	Sucrose	Melamine
Calcineurin inhibitors (category)	SGLT-2 inhibitors (category)	Phenylbutazone
Colistin	Statins (category)	Taxus celebica
Dextran	Sulfadiazine	Uno delgatta
Gemcitibine	Quinolones (category)	
Hydroxyethyl starch	Topiramate	***Environmental compounds***
Ifosfamide	Vancomycin	Bismuth
Immunotherapies	Zonisamide	Cadmium
Interleukin-2		Copper
Mannitol		Germanium
Mesalamine		Hydrocarbons
Methotrexate		Lead
Methoxyflurane		Mercury
Mitomicin		Silicon
mTOR inhibitors (category)		Uranium

This comprenensive list of nephrotoxins was adapted from Perazella MA and includes medications and compounds likely to be encountered by patients in the inpatient and ambulatory settings [44]

ACE angiotensin-converting enzyme, *ARB* angiotensin II receptor blocker, *NSAID* nonsteroidal anti-inflammatory drug, *COX* cyclooxygenase

that [36, 38, 44]. Table 1 provides a general list of nephrotoxic compounds, grouped by therapeutic category; this table is based on the work of Perazella and contains a comprehesive list of pharmaceuticals as well as the natural compunds and environmental toxins described later. The NINJA list of nephrotoxins focuses specifically on medications prescribed to hospitalized children. This list is subject to evidence-based review and refinement [39]; Table 2 provides the most current list alphabetically [36].

Naturally Occurring Nephrotoxins

One category of naturally occurring nephrotoxins which are of great importance from a global health standpoint are animal and insect venoms. For example, the brown recluse spider (*Loxosceles reclusa*), which is endemic to the Southcentral United States, is well known for the toxicity of its bite [45]; there are more than 100 species of *Loxosceles* spiders and systemic loxoscelism is common throughout South America [46]. In the tropical and sub-tropical regions of the world, venomous snakes account for millions of bites annually, with significant morbidity and mortality [47]. Scorpion envenomation is more common in parts of Central and South America, Northern Africa, and the Middle East [48]. Envenomation due to contact with the bristles of the *Lonomia obliqua* caterpillar has been seen with increasing frequency, possibly due to environmental changes in Brazil [49]. The toxicity of Hymenoptera (bees, wasps, ants) stings may result from hundreds of stings or as few as 20. Despite the existence of >150,000 species of Hymenoptera, generally only envenomation from the honeybee, yellow jacket, and giant hornet are considered clinically relevant from a nephrotoxcity standpoint

Table 2 Nephrotoxins Monitored by NINJA Initiative

Acyclovir	Gentamicin*	Naproxen
Ambisome	Ibuprofen	Pamidronate disodium
Amikacin*	Ifosfamide	Pentamidine
Amphotericin B	Indomethacin	Piperacillin
Aspirin	Iodixanol (Visipaque)	Piperacillin/Tazobactam
Captopril	Iohexol (Omnipaque)	Polymixin B
Carboplatin	Iopamidol (Isovue)	Sirolimus
Celecoxib	Iopromide	Sulfasalazine
Cidofovir	Ioversol	Tacrolimus
Cisplatin	Ioxaglate meglumine/sodium	Tenofovir
Colistimethate	Ioxilan	Ticarcillin/clavulanic acid
Cyclosporine	Ketorolac	Tobramycin*
Deferasirox	Lisinopril	Topiramate
Diatrizoate meglumine	Lithium	Valacyclovir
Diatrizoate sodium	Losartan	Valganciclovir
Enalapril	Mesalamine	Valsartan
Enalaprilat	Methotrexate	Vancomycin*
Foscarnet	Mitomycin	Zoledronic acid
Ganciclovir	Nafcillin	Zonisamide

This is the curated list of medications administered to hospitalized children curated by the NINJA collaborative. Exposure constitutes the concomitant administration of 3 of these 57 agents or the administration of highly nephrotoxic agents (*) for an extended period of time (greater than or equal to 3 days). This represents the current list as of December 31st 2020

[50]. Renal injury from envenomations can be due to a variety of mechanisms including hemodynamic changes, microvascular thrombosis, AIN or direct cellular toxicity.

Botanicals are another naturally occurring source of nephrotoxicity; these compounds cause renal injury by intentional consumption as a food source (often to excess) or as a part of traditional healing methods. For example, excessive ingestion of star fruit [51], rhubarb [52], cashew pseudofruit [53], or djenkol beans [54] can cause acute crystal nephropathy. Traditional Chinese medicines may not be solitary substances, but rather complicated compounds whose toxicity is due to the presence of aristolochic acids, alkaloids, flavonoids, and/or anthraquinones [55]. Aristolochic acids in particular are not limited to Chinese therapies as products containing this compound are consumed around the world to treat a variety of conditions and have been linked to interstitial nephritis and renal failure [56]. The castor bean plant, infamous due to its derivative ricin, has also long been used as phytotherapy by many cultures [57]. A renewed interest in mycology has spurned an increase in *Amanita phalloides* (poison mushroom) ingestion with most cases being accidental due to misidentification [58]. These plant toxins, once ingested, cause cellular apoptosis, necrosis, and microvascular thrombosis [59, 60].

Environmental Nephrotoxins

Environmental hazards where humans routinely live, work, and play can pose a daily threat and have been linked to millions of deaths [61]. Ethylene glycol poisoning from antifreeze ingestion has received significant attention, with campaigns focused on decreasing exposure and mitigating the adverse effects including crystalluria [62]. Heavy metal poisoning, such as that that seen with lead, can occur as an occupational exposure. Alternatively, although nonoccupational exposures were thought to have been addressed decades ago by eliminating lead-based paint, pipes, and gasoline, such exposures continue to this day; the recent water crisis in Flint, Michigan (Unites States) is a reminder of this fact [63]. Outside of the United

States, currently less than 50% of countries have legal restrictions in place to limit lead-based paints; furthermore, exposure through contaminated ground water, traditional medicines, and soil remains a global health concern. Other examples of heavy metal nephrotoxins include the cadmium and mercury found in fuel combustion and some foods; uranium and arsenic have been detected in contaminated soil and water. Exposure to these heavy metals can cause tubular dysfunction acutely and progressive chronic kidney disease (CKD) with ongoing exposure [61]. Finally, there is a strong link between residing in agricultural communities and kidney disease [64]. The etiology is likely multifactorial, however, pesticides are known to have numerous adverse effects in humans [65]. Unfortunately, determining which specific agricultural chemicals are nephrotoxic is challenging as comunities are often exposed to multiple pesticides concurrently [61]. There are a number of drugs of abuse, such as inhaled solvents, heroin, and cocaine which are known to have nephrotoxic potential. The toxicity of synthetic cannabinoids [66], synthetic cathionones, and 3,4-methylenedioxymethamphetamine (MDMA, ectasy) are well described but may vary as unique clusters of injury imply a shifting composition of the products [67]. More recent data suggests anabolic steroid use may be associated with CKD as well [68].

Mechanisms of Nephrotoxicity

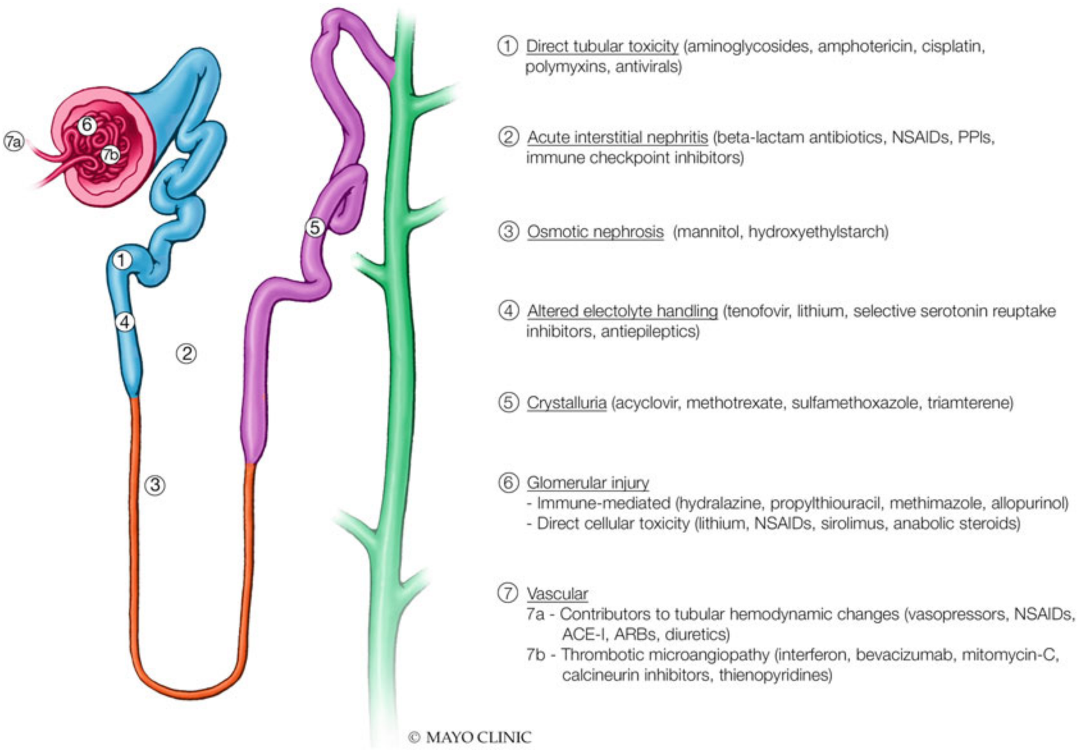
One of the most important approaches used to categorize and catalog nephrotoxins is based upon the mechanism of toxicity (Fig. 1). Understanding the manner by which injury occurs helps providers prevent, mitigate, and potentially treat nephrotoxicity. For example, the use of multiple medications with comparable mechanisms of injury may lead to a synergistic risk for complications [69]. Alternatively, if one knows that an agent causes kidney damage via urinary crystal formation, increasing urine output and diluting the concentration of the drug may help reduce injury. Furthermore, although no treatments exist for nephrotoxicity once it occurs, an understanding of the underlying mechanisms of injury will allow for the development of targeted therapeutics in the future. It is important to note that while certain drugs and their metabolites classically present with one specific mechanism of injury, many will present variably. For example, vancomycin-associated nephrotoxicity may manifest as ATN, AIN, or cast nephropathy [70–72]; similarly, NSAIDs may cause kidney injury via a number of different pathways. Finally, the ultimate presentation of injury is in many respects dependent on patient factors and clinical context.

Pseudo-nephrotoxicity

Nephrotoxicity results from extrinsic or intrinsic deleterious effects of a toxin on kidney structure or function. At the bedside, one of the early warning signs is a rise in the endogenous serum biomarker creatinine. Serum creatinine is a freely filtered small molecule that exhibits an inverse relationship with kidney function. A fraction of serum creatinine is also eliminated through active tubular secretion via several transporters including the organic cation transporter 2 (OCT2) [73]. The drug trimethoprim is an OCT2 inhibitor which inhibits tubular secretion of creatinine, increasing serum creatinine concentrations without directly damaging the kidney [74]. This is an example of “pseudo-nephrotoxicity.”

Indirect Nephrotoxicity

In certain cases, medications may not be directly nephrotoxic but rather they contribute to systemic disease which, in turn, causes kidney damage. Rhabdomyolysis is an example of a systemic syndrome which results in indirect nephrotoxicity [75]. Several mechanisms contribute to AKI associated with rhabdomyolysis including vasoconstriction, direct ischemic injury, proliferation of free radicals, and tubular obstruction associated with myoglobinuria [76]. Hydroxy-methyl-glutaryl-coenzyme A (HMG-CoA) reductase inhibitors or “statins” are not classically thought of as nephrotoxins. However, when used in



① Direct tubular toxicity (aminoglycosides, amphotericin, cisplatin, polymyxins, antivirals)

② Acute interstitial nephritis (beta-lactam antibiotics, NSAIDs, PPIs, immune checkpoint inhibitors)

③ Osmotic nephrosis (mannitol, hydroxyethylstarch)

④ Altered electolyte handling (tenofovir, lithium, selective serotonin reuptake inhibitors, antiepileptics)

⑤ Crystalluria (acyclovir, methotrexate, sulfamethoxazole, triamterene)

⑥ Glomerular injury
- Immune-mediated (hydralazine, propylthiouracil, methimazole, allopurinol)
- Direct cellular toxicity (lithium, NSAIDs, sirolimus, anabolic steroids)

⑦ Vascular
7a - Contributors to tubular hemodynamic changes (vasopressors, NSAIDs, ACE-I, ARBs, diuretics)
7b - Thrombotic microangiopathy (interferon, bevacizumab, mitomycin-C, calcineurin inhibitors, thienopyridines)

© MAYO CLINIC

Fig. 1 Mechanisms of Nephrotoxic Injury. The primary mechanisms by which nephrotoxins cause kidney injury are highlighted along the length of the nephron segement. Some agents, such as aminoglycosides directly injure renal tubules (1). Others, such as some beta-lactam antibiotics, induce an acute interstitial nephritis (2). Medications such as mannitol may cause osmotic nephrosis which is marked by tubular swelling and death (3). Many substances have minimal impact on filtration but instead disturb fluid and electolyte homeostasis (4). Acyclovir and other agents which are insoluble in urine may precipitate in the tubules causing cell injury and obstruction to urinary flow (5). Although uncommon, specific pharmaceuticals can cause immune-mediatied glomerular injury or direct damage to podoctes (6). Finally, many medications adversely affect intrarenal hemodymanics (7a) or renal blood flow (7b). NSAID nonsteroidal anti-inflammatory durg, PPI proton pump inhibitor, ACE-I angiotensin-converting enzyme inhibitor, ARB angiotensin II receptor blockers. settings where the risk for rhabdomyolysis is heightened, such as in combination with a macrolide antibiotic or in a patient with a genetic variant at the *SLCO1B1* transporter, their use can lead to kidney damage [69, 77, 78].

Vascular Complications

The kidney receives approximately 25% of the cardiac output. It is therefore sensitive to factors that influence systemic hemodynamics. Excessive exogenous fluid administration may increase venous pressure in the kidney, leading to interstitial edema which can reduce renal blood flow, glomerular filtration rate (GFR), and lead to additional salt and water retention [79]; indeed, fluid overload in critically ill children has been associated with major adverse kidney events and poorer outcomes [80, 81]. The opposite effect, iatrogenic intravascular volume depletion due to excessive diuresis, may decrease effective circulating arterial blood volume and compromise kidney perfusion. Drugs that lead to vasoconstriction or alter transglomerular pressure can also contribute to this phenomenon. Vasopressors such as norepinephrine may increase the risk for AKI due to renal vasoconstriction [8]; alternatively, vasopressors may mitigate systemic hypotension and restore effective kidney perfusion [82]. Similarly, calcineurin inhibitors lead to dose-dependent vasoconstriction of the afferent and efferent arterioles [83, 84]. Renin-angiotensin-aldosterone system (RAAS) inhibitors (e.g., ACE inhibitors and angiotensin II receptor blockers or ARBs) decrease the vasoconstrictive effect of angiotensin II at the efferent arteriole and reduce glomerular filtration pressure. Similarly, NSAIDs inhibit prostaglandin synthesis which decreases afferent arteriolar vasodilation with a comparable effect on glomerular pressures and GFR [23]. The hemodynamic effects of these medications are especially problematic in patients with reduced baseline kidney perfusion pressures such as those with shock or preexisting intravascular volume depletion. Perturbation of the vasoconstriction/vasodilatation balance may promote ischemia and loss of GFR, however, in many situations, the decrease in GFR does not necessarily reflect cellular damage. It is also important to note that some medications cause endothelial injury which manifests as thrombotic microangiopathy (TMA). Drug-associated TMA may be seen with anti-angiogenic drugs, chemotherapeutics, calcineurin inhibitors, interferon, thienopyridines, and quinine [85–89].

Glomerular Disease

Several drugs are associated with immune-mediated glomerular disease through production of autoantibodies. Manifestations include ANCA-associated vasculitis with necrotizing, crescentic, pauci-immune glomerulonephritis, drug-induced lupus, and drug-associated membranous nephropathy; common examples of drugs that may lead to immune-mediated glomerular diseases include hydralazine, propylthiouracil, methimazole, cocaine, allopurinol, and procainamide [10, 90]. Drugs may also cause glomerular disease via direct cellular toxicity at the level of the podocyte, the endothelial cell, or the mesangial cell; drug-induced podocytopathies include the minimal change disease (MCD) and focal segmental glomerulosclerosis (FSGS) associated with interferon, anabolic steroids, bisphosphonates, and sirolimus [90–92]. Lithium and NSAIDs may also lead to podocytopathies, but these are not the most common manifestations of nephrotoxicity with these drugs.

Direct Tubular Toxicity

Drugs or their metabolites may directly damage tubular cells via mitochondrial injury, oxidative stress, or DNA damage that can lead to apoptosis and necrosis [71]. Cisplatin, an antineoplastic medication, is well known to be associated with this pattern of injury. Cisplatin is freely filtered at the glomerulus, reabsorbed into proximal tubular cells via active transport, and secreted into tubular cells by the basolateral OCT2. While in tubular epithelial cells, the parent drug and a nephrotoxic metabolite lead to direct cellular damage [84, 93]. Aminoglycosides (e.g., gentamicin, amikacin) undergo glomerular filtration, endocytosis into tubular cells, and intracellular accumulation which can trigger an injury cascade resulting in cell death [71]. Other medications known to cause direct tubular toxicity include amphotericin deoxycholate, polymyxins, cidofovir, adefovir, foscarnet, tenofovir, and radiocontrast agents [25, 71, 84].

Acute Interstitial Nephritis

Drug-associated AIN is thought to be a cell-mediated immune response, analogous to a type 4 (delayed type) hypersensitivity reaction [94]. In AIN, drugs may act as haptens to modify the endogenous response to native renal proteins or induce an autoimmune reaction to the tubular basement membrane through molecular mimicry [95]. Drugs may also trigger systemic immune-activation that leads to deposition or sequestration of immune complexes in the kidney interstitium [94, 96]. Interstitial infiltration by lymphocytes, macrophages, eosinophils, and mast cells leads to inflammation and eventually fibrosis [71]. On kidney biopsies, the primary pathologic findings include interstitial inflammation, edema, and tubulitis [90]. Drugs and drug classes associated with AIN include beta-lactam antibiotics, rifampin, sulfonamides, NSAIDs, proton pump inhibitors, and immune checkpoint inhibitors [95].

Osmotic Nephrosis

Drugs such as mannitol, hydroxyethyl starch, immunoglobulins (predominantly those containing sucrose), and dextrans may lead to osmotic nephrosis. In these cases, drug molecules undergo pinocytosis, cellular accumulation, leading to cells swelling, vacuolation, and obstruction of the tubular lumen [71].

Crystalluria/Nephrolithiasis

Certain medications or their metabolites are insoluble in the urine and can result in crystalline nephropathy and renal calculi [9, 71]. Crystals typically form in the distal aspects of the tubules, obstruct urine flow, and lead to injury of the surrounding kidney tissue. Crystal formation is typically exacerbated by volume depletion, reduced urinary flow rates, high drug doses, rapid drug infusion rates, and altered urine pH. Drugs causing crystalline nephropathy include acyclovir, methotrexate, sulfamethoxazole, indinavir, atazanvir, triamterene, ciprofloxacin, and ethylene glycol [71]. Systemic syndromes may also lead to crystal deposition in the kidney. One such example is the tumor lysis syndrome. Systemic chemotherapy for a rapidly proliferating hematologic malignancy may trigger hyperuricemia, metabolic acidosis, and an increase in the calcium-phosphorous product. A net consequence of these systemic effects is AKI from inflammation, crystal deposition, renal vasoconstriction, and impaired autoregulation [97].

Altered Electrolyte Handling

Drugs may alter how the kidney handles phosphate, glucose, magnesium, potassium, sodium, or water [9]. Specific patterns may include the syndrome of inappropriate antidiuretic hormone (SIADH), diabetes insipidus, or an acquired Fanconi syndrome. Drugs causing this type of kidney dysfunction include lithium, tenofovir, ifosfamide, selective-serotonin reuptake inhibitors, anti-epileptics, and vincristine [98].

Specific Nephrotoxic Medications

While a comprehensive discussion of every nephrotoxin is beyond the scope of this chapter, an in-depth discussion of several injurious substances will help underscore many of the general concepts described here within. Additionally, these medications will serve as the basis for the discussions around prevention, mitigation, and treatment of nephrotoxicity which are laid out later in the chapter. As such, this section will focus on pharmaceutical agents that are commonly used, extensively studied, have a well understood mechanism of injury, or an effectively described epidemiology; particular attention was paid to medications presenting with the AKI phenotype.

Vancomycin

Vancomycin is a glycopeptide antibiotic which inhibits cell wall formation. Although clinically introduced in 1958, nephrotoxicity limited its use which was “reserved for the treatment of potentially life threatening infections which cannot be treated with less toxic antibiotics” [99, 100]. However, antibiotic resistance to methicillin prompted increasing usage as the purported benefits began to outweigh concerns about toxicity [101, 102]. Since then, vancomycin usage has increased and it is now one of the most commonly prescribed antibiotics for treatment of gram-positive organisms [103]. Although it can be given orally or intravenously, most of its nephrotoxicity has been ascribed to intravenous (IV) administration, which will be the focus of this section.

Most of our mechanistic understanding of vancomycin-associated nephrotoxicity is from animal models. These data suggest that vancomycin accumulates in the proximal tubule cells, specifically in the lysosomes [104]. Once present, vancomycin causes oxidative stress, autophagy, and apoptosis [100, 104]. The nephrotoxic phenotype of vancomycin is AKI; compared with patients receiving a non-glycopeptide antibiotic, those prescribed vancomycin experience a relative risk for AKI of 2.45 (95th CI 1.69–3.55) [105]. Although the incidence of AKI in patients receiving vancomycin seems to be highly dependent on drug and patient factors, the incidence ranges from 5% to 43% [106]. Patient-related risk factors include obesity, CKD, severity of illness, and concurrent administration of other nephrotoxic agents [100]. Obesity may increase AKI risk in patients receiving vancomycin due to a discrepancy between actual body weight and ideal body weight; use of a more dosing-appropriate weight and drug exposure monitoring can mitigate this risk [107, 108]. Patients with preexisting CKD are at increased risk for developing vancomycin-associated nephrotoxicity, primarily since clearance is directly related to GFR. Patients with lower GFRs clear vancomycin less effectively, increasing systemic exposure and potential for injury; the lack of excellent dosing data in patients with CKD exacerbates this risk [109]. Similarly, though the causal relationship is poorly understood, patients requiring critical care have increased risk for vancomycin-associated injury compared to those receiving acute care [110]. Finally, vancomycin nephrotoxicity risk is increased by coadministration of other known nephrotoxic agents which is relatively unsurprising given our understanding of nephrotoxic burden. However, one particular interaction warrants additional discussion. As the bactericidal effect of vancomycin is isolated primarily to gram-positive organisms, when an infectious agent has not been identified and broad coverage is required, it is frequently coadministered alongside an agent with potent gram-negative coverage. Notably, the combination of vancomycin and piperacillin-tazobactam has been associated with particularly increased AKI risk. In one single center study, administration of vancomycin and piperacillin-tazobactam was associated with a 6.8-fold (95th CI 1.5–30.9) increased risk for AKI compared with co-administration of vancomycin and meropenem [111]. In a meta-analysis of six studies in adults, the combination of these two antibiotics was associated with an increased risk compared to administration of vancomycin alone (OR 2.77, 95th CI 1.94–3.96) [112]. A systematic review found a similar association but highlighted the fact that the majority of studies are small, retrospective, and unadjusted [113]. This association has been described specifically in pediatric populations as well; a meta-analysis of studies involving children found increased AKI risk with concomitant vancomycin and piperacillin-tazobactam administration [114].

Drug-related risk factors include trough levels or area under the curve (AUC) determinations (dose/exposure proxy), duration of therapy, and method of administration [100]. The best available data suggests that in vivo drug exposure strongly affects vancomycin nephrotoxicity risk [100, 106]. The most commonly used method of assessing systemic exposure is monitoring of trough concentrations. Levels higher than 15 mg/L have been associated with higher AKI risk, which is potentially problematic given historical recommendation to target trough levels of 15–20 mg/L in severe infections in order to insure adequate AUC to minimum inhibitory concentration (MIC) ratios. In children, data suggest that lower trough levels are adequate to achieve the required AUC; however, current guidelines recommend using AUC rather than trough level monitoring whenever possible [115, 116]. Regardless of the method used to determine exposure, higher exposure increases AKI risk. Another way to measure exposure is duration of therapy. One meta-analysis found that courses of 7–14 days duration were associated with higher AKI risk; indeed, most AKI events occurred after 7 days of therapy [106]. Finally, there is some data that continuous infusions of vancomycin decrease nephrotoxicity risk compared to intermittently dosed regimens [100, 115].

Aminoglycosides

Although several aminoglycosides exist, the most commonly prescribed are amikacin, gentamicin, and tobramycin. Typically, they are used to treat infections with aerobic, gram-negative bacteria; however, they have some gram-positive activity as well. Aminoglycosides, which were introduced in the 1940s, prevent protein synthesis by binding to ribosomal subunits [25]. They are freely filtered at the glomerulus and accumulate in proximal tubular cells; elevated drug concentrations cause injury via a direct cytotoxic effect [25]. The nephrotoxic phenotype of aminoglycosides is AKI. Studies in adults and children suggest that AKI rates can be as high as 20–33% [11, 25, 117, 118]. Although data suggest that severity of illness and comorbid conditions increase AKI risk, studies using modern definitions of AKI suggest that at least 20% of noncritically ill children receiving aminoglycosides for more than 5 days will develop AKI [11, 25, 117]. Aminoglycoside-associated AKI develops 5–7 days after initiation and, unlike many other causes of AKI, tends to be non-oliguric [11]; data suggest that aminoglycosides may damage the distal tubule and collecting duct in addition to the proximal tubule, thereby inhibiting urinary concentration [119, 120]. In addition to AKI, patients with aminoglycoside nephrotoxicity can develop hypokalemia, hypophosphatemia, hypomagnesemia, and even a Fanconi-like phenomenon [11, 121]; these findings are likely reflective of the tubular damage the drug causes.

As is the case with vancomycin, there are patient and treatment-specific risk factors for aminoglycoside-associated nephrotoxicity. With regard to patient-related risks, advancing age has been shown to increase risk, however, this phenomenon is exclusive to elderly populations and is not relevant to pediatric medicine [122]; the AKI risk seems similar from neonates to adolescents and young adults [11]. Additional risk factors include underlying severity of illness and comorbid disease; patients with sepsis, CKD, liver failure, and leukemia have been described as at increased risk [11, 121, 123, 124]. Interestingly, it is not clear whether CKD is a causative risk factor or that the reduced GFR in these patients increases the risk for overdosing the medication. Reduced effective circulating volume and lower kidney perfusion pressures may increase AKI risk in patients receiving aminoglycosides [122, 125, 126]. Finally, the concomitant administration of other medications, especially nephrotoxins, increases risk [11, 121, 127].

Beyond patient-specific risk factors, there are some risk factors specific to the administration of the aminoglycoside itself. One such risk is the duration of therapy. As stated above, aminoglycoside-associated AKI is less common when courses are shorter than 5–7 days; longer courses increase exposure, proximal tubular accumulation, and nephrotoxicity [11, 121]. Another factor is the drug level; while AKI may occur with medication levels within the target therapeutic range, higher levels increase this risk in most studies [128]. Interestingly, many have recommended giving a larger dose of aminoglycosides once a day, rather than smaller doses at scheduled intervals throughout the day. While data in animal studies suggested a lower risk of nephrotoxicity, this has not been borne out clinically in most studies and meta-analyses [129, 130]. There does, however, remain a theoretical benefit and once daily dosing is no less effective. The method of administration also affects risk. While AKI has been described with inhaled aminoglycosides, the risk seems to be substantially lower than that of IV administered agents [131, 132]. Finally, the choice of aminoglycoside influences AKI risk and the nephrotoxicity of the agents is not the same at equipotent doses. Although the data is somewhat mixed, the nephrotoxicity of amikacin is less than tobramycin which, in turn, is less than gentamicin [121].

Intravenous Contrast

Iodinated contrast media has long been considered a nephrotoxin. The pathogenesis of kidney injury-related to administration of these agents is incompletely understood. The best data available suggest that at least two primary mechanisms are responsible [133, 134]. First, contrast media, perhaps via increased release of endothelin or adenosine (vasoconstrictors) and inhibition of prostaglandins and nitric oxide (vasodilators), causes renal vasoconstriction and ischemic injury [133, 134]. Secondly, there is evidence that contrast causes direct tubular toxicity [133–135]. Regardless of the underlying pathophysiology, the end result is a nephrotoxic phenotype consistent with AKI. Typically, the creatinine increases 24–48 h after contrast administration; resolution of AKI commonly occurs within 5–10 days [133–135]. The AKI is commonly non-oliguric and may be associated with a prerenal fractional excretion of sodium (FENa < 1%) [136].

Early studies suggest that the incidence of contrast-associated AKI was 3–14.5% [135]; incidence is highly associated with underlying risk factors, and some studies suggest the incidence among those with multiple risk factors is 20–30% [137]. However, more recent, well-designed studies of newer agents suggest that in the absence of significant risk factors, the incidence may be much lower than historically thought. The newer data suggesting a lower nephrotoxic risk for contrast has led to a transition away from the concept of contrast-induced nephropathy or AKI to contrast-associated nephropathy or AKI [138]. This sematic change removes the causal concept. In many situations, patients who receive contrast have other AKI risk factors precluding a true causal link to be drawn to the contrast itself. For an episode of AKI to be considered contrast-induced, it must be possible to exclude all other causes of AKI, allowing the causal association to be drawn.

Several risk factors for contrast-associated AKI have been described. First generation iodinated contrast agents were both ionic and hyperosmolar (relative to plasma with osmolarities of >1400 mOsm/kg) [139]. Newer agents include both low-osmolar (500–800 mOsm/kg) and iso-osmolar agents (~300 mOsm/kg); the low-osmolar agents may be ionic or nonionic and the single currently available iso-osmolar agent is nonionic [137]. When compared with the newer low- and iso-osmolar agents, the original hyperosmolar agents are associated with increased nephrotoxic risk [140]; this, in part, may explain the fact that newer studies identify a lower risk of nephrotoxicity with contrast administration. In addition to the type of agent used, the dose administered seems to affect AKI risk with higher doses associated with greater risk [141]. Finally, the type of procedure may impact risk as intra-arterial administration of contrast is associated with greater AKI risk than intravenous administration [133]. Patient-specific risk factors may include administration of additional nephrotoxins, hypovolemia of any cause (dehydration, heart failure, sepsis), albuminuria, diabetes mellitus, and CKD [138].

The relationship between CKD or GFR and contrast-associated nephrotoxicity warrants additional discussion. It is clear that AKI risk is higher in patients with higher CKD stage or lower GFRs [138, 142, 143]. For example, the incidence of contrast-associated AKI has been estimated as ~5% for GFR > 60 mL/min/1.73m^2, 10% for GFR 45–59 mL/min/1.73m^2, 15% for GFR 30–44 mL/min/1.73m^2, and 30% for GFR < 30 mL/min/1.73m^2 [138]. Interestingly, the risk in children may be lower than these rates which were primarily based on adult studies. Two large retrospective studies in children found no increased risk for AKI following intravenous contrast administration regardless of GFR and ambulatory/inpatient setting [144, 145].

Nonsteroidal Anti-inflammatory Drugs

The use of NSAIDs dates back over 3500 years ago to the African continent with the Sumerians using the extracts of willow leaves to treat pain. This extract has been used globally by the Greeks and the Romans in Europe, by the Chinese in Asia, and by Native Americans in North America [146]. The first formal extraction of the active component of the willow tree, salicin, is credited to the Italian pharmacists Fontana and Rigatelli in 1824. Chemical synthesis of acetylsalicylic acid was accomplished in France before the method was patented by a German team in 1874. Twenty-five years later, in a Bayer laboratory, a reliable process for obtaining the purified form was created and the name aspirin was coined [147]. There are now six major classes of NSAIDs with over fifty different formulations and combinations. NHANES III reported that approximately 62% of the US population over the age of 17 took NSAIDs, and it is likely that drugs in the NSAID class are the most ubiquitously administered nephrotoxins worldwide [148].

NSAIDs inhibit the ability of cyclooxygenase (COX) to convert arachidonic acid to prostaglandins and thromboxane. There are two isoforms of COX, COX-1 and COX-2; COX-1 is present in most tissues and is responsible for the basal production of prostaglandin synthesis for homeostatic functions while COX-2 is constitutively expressed primarily in the brain, kidney, ovary, and uterus [149]. Notably, COX-2 is inducible by pro-inflammatory cytokines such as IL-1 and TNF-A. While the primary phenotype of NSAID nephrotoxicity is AKI, disruption of homeostatic physiology can lead to electrolyte disturbances (hyperkalemia or hyponatremia), edema, and papillary necrosis [150–152]. It is likely that the nonspecific nature of COX blockade and the resultant interference with prostaglandin synthesis is primarily responsible for the nephrotoxicity of NSAIDs. The prostaglandins PGE_2 and PGI_2 are responsible for renal vasodilatation, which increases renal blood flow and GFR. Disruption of this vasodilatory process becomes more clinically apparent in scenarios where renal perfusion is already compromised (e.g., heart failure, intravascular volume depletion, sepsis) or in cases where vasoconstricting hormones, such as angiotensin II, are also upregulated (e.g., concomitant administration of ACE inhibitors) [153]; in these cases, NSAID administration may lead to a substantial decrease in GFR and overt AKI. Although the specific COX-2 inhibitors were developed to mitigate the adverse effects seen with nonselective COX inhibition, it turns out that COX-2 production is upregulated in hypovolemia and this enzyme plays an outsized role in the renal protective response. Thus, the risk of AKI with COX-2 inhibitors is similar to that of nonselective inhibitors [154]. While NSAIDs can be used safely when attention is paid to their potential for nephrotoxic risk, AKI occurs in up to 5% of patients receiving these agents [1, 22, 151]; this risk may be exacerbated by any sort of intravascular volume depletion as described above, as well as in the setting of reduced GFR or CKD [44, 94]. In the setting of severe dehydration or massive overdose NSAIDs can even cause acute renal papillary necrosis. The vascular blood supply in the renal papillae is highly dependent on prostaglandin production and impaired production can cause ischemia. Clinically, these patients may present with abdominal or flank pain and gross hematuria. While renal function may return to baseline, maximal concentration of the urine may be impaired due to the loss of the deep loops of Henle [151].

Prostaglandins modulate sodium and water handling and NSAIDs use can lead to water and sodium retention [155]. This effect is particularly pronounced in patients with preexisting positive sodium and water balance such as those in heart failure or with nephrotic syndrome. Although both sodium and fluid are retained, on balance NSAIDs tend to cause hyponatremia, especially in those with generous free water intake [156]. Hyperkalemia is uncommonly seen with NSAID use unless other agents prone to cause potassium retention are administered concomitantly (e.g., potassium-sparing diuretics, potassium supplements, ACE inhibitors, or trimethoprim therapy) [151]. In these cases, inhibition of PGE_2 and PGI_2 reduces the release of renin and aldosterone, further impairing potassium excretion. Hyperkalemic risk may also be exacerbated by higher sodium reabsorption rates as reduced sodium delivery to the distal tubule also decreases effective potassium excretion [155]. Finally, NSAIDs can lead to AIN which may present similarly to AKI. However, patients with AIN are more likely to have systemic symptoms including fever, joint or abdominal pain, and rash [22]. While sterile leukocyturia may be present, this is not a ubiquitous finding and definitive diagnosis requires a kidney biopsy. Distinguishing between AKI and AIN is important as management between the conditions may differ [157].

Renin-Angiotensin-Aldosterone System Inhibitors

The RAAS is primarily responsible for regulating systemic vascular resistance and effective circulating volume. Inhibitors of the RAAS, including ACE inhibitors and ARBs, are commonly prescribed and extraordinarily effective; they are considered first line antihypertensives, they reduce mortality in the setting of heart failure, and slow progression of proteinuria-related kidney disease of diabetic and nondiabetic origin. Despite their effectiveness, they have several side effects including a reduced GFR and are widely considered nephrotoxic by prevailing adult and pediatric nephrology guidelines [36, 71]. When seen, the most common nephrotoxicity phenotype of RAAS blockade is AKI.

The mechanism of AKI in the setting of ACE inhibitor and ARB exposure is hemodynamic alteration of glomerular vasculature as they preferentially inhibit vasodilatation of the afferent arteriole [158]. This effect, when combined with a drop in systemic blood pressures, reduces renal perfusion and GFR, leading to higher serum creatinine levels diagnostic of AKI [159]. Notably this effect is more pronounced in the setting of already reduced effective circulating volume (dehydration, hepatorenal syndrome, sepsis, heart failure, etc.) and the presence of other nephrotoxins (NSAIDs) [160]. For example, in high-risk adults (vascular disease and severe diabetes mellitus), subjective "renal dysfunction" severe enough to require drug discontinuation occurred in 10.2% and 10.6% of patients receiving ramipril (ACE inhibitor) and telmisartan (ARB), respectively [161]. Similarly, in adults undergoing cardiothoracic surgery, pre-operative use of RAAS inhibitors increased the risk for postoperative AKI [162]. In children, a retrospective analysis of 332 patients who received an ACEI found that 20 (6%) experienced a doubling of serum creatinine (KDIGO Stage 2 AKI) [163]; by comparison, the prevalence of AKI was 21% in children receiving ACEI following cardiac surgery [164]. It is important to note that this hemodynamic effect is typically reversible with drug cessation and there is some debate as to the long-term renal risk associated with administration of these medications [165]; some have even advocated for maintaining these medications in the setting of early AKI [158, 159]. As such, it is important to balance the long-term cardiovascular and renal benefits afforded by these medications with the potential for acute episodes of nephrotoxicity. However, the effect on renal perfusion is clear and with the increasing complexity seen in pediatric disease management, it is important to think of these medications as capable of causing or exacerbating nephrotoxic AKI, especially in the setting of substantial nephrotoxin burden.

Prevention and Management

There is no pharmacologic therapy capable of treating or curing nephrotoxic AKI once it develops. However, delayed recognition and intervention may result in disease progression and irreversible damage. Thus, the cornerstones of management are prevention, risk minimization, early identification, and severity mitigation (Fig. 2). The pathophysiologic principles described previously in this chapter form the foundation of management strategies and a thorough understanding of the manner in which substances cause injury will help guide practitioners as they navigate the complex interplay between a patient's condition, underlying comorbidities and disease related risk factors, and polypharmaceutical nephrotoxic burdens. Furthermore, a more detailed understanding of the most commonly prescribed agents, as highlighted in the previous section, will allow for optimization of therapeutic approach even in the most nuanced clinical scenarios.

If, indeed, the mechanism of injury is known, interventions capable of mitigating damage may exist. For example, if NSAID-associated AKI fails to improve following discontinuation of the medication, a renal biopsy looking for AIN may be indicated. Although their effectiveness is somewhat debated, if AIN is confirmed, corticosteroids may be beneficial [95, 166–168]. Acyclovir provides another excellent example of this concept. As the mechanism of injury is urinary crystal formation, volume expansion and/or generation of brisk urine flow may help prevent crystal precipitation and tubular obstruction or, at a minimum, reduce its severity [169]. Notably, while diuretics have been used to augment urine output, they really should only be used to manage volume overload (if it occurs) as forced diuresis without adequate volume expansion may cause hypovolemia, decrease renal perfusion, and worsen renal injury [42]. Additionally, some nephrotoxic medications such as methotrexate

Fig. 2 Approaches to the management of nephrotoxins and nephrotoxic AKI. Although specific treatments do not exist for nephrotoxic injury once it develops, successful strategies have been developed to guide the care of patients requiring administratoin of these substances. The earliest possible intervention is avoidance (primary prevention). If the risk of the medication outweighs the benefit, it should not be administered; likewise, if a less injurious but equally effective alternative is available, substitution should be considered. Secondly, if nephrotoxins are indeed required, it is of paramount importance to minimize the dose and durtation of individual medications as well as to limit the overall, comprehensive nephrotoxin burden. Third, if specific preventative strategies are available (e.g., volume resusitation with acyclovir administration), they should be proactively deployed. Should injury occur, it is important to identify the presence (diagnose) and severity (stage) of AKI as well as to monitor for disease progression. Once AKI develops, all other potential AKI risk factors should be evaluated and eliminated or modified to the extent possible. Finally, among all patients who develop injury, it is imperative that these patients receive appropriate follow-up care for their adverse event; this includes assessing AKI recovery and evaluating for long-term sequelae (e.g., hypertension, proteinuria, CKD). AKI acute kidney injury. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved)

and sulfadiazine are known to have higher solubility in an alkaline urine (pH >7); thus, administration of bicarbonate containing intravenous fluids may prevent crystal formation and support dissolution of existing crystals. However, caution must be exercised as serum electrolytes shifts and urinary calcium phosphate precipitation are potential consequences of alkaline fluid administration; it is imperative that the treatment is no worse than the disease [170]. It is important to note that a solid understanding of pathophysiology is not always sufficient, and some diseases continue to wait for effective treatments. Contrast nephropathy is a great example. Although the manner in which injury occurs is fairly well understood, attempts to prevent contrast-associated AKI with n-acetylcysteine and other antioxidants have proven fruitless [171, 172]. Some agents, such as the adenosine receptor antagonists (theophylline and aminophylline) have shown an effectiveness in observational studies that has not always been confirmed in controlled trials [173–175]. Despite many setbacks, interest remains high in developing therapeutics with the goal of preventing or treating AKI of all causes. Not only will the pathophysiology of nephrotoxic AKI guide the development of targeted therapeutics, but it will also allow providers to more efficiently cross-purpose agents found to be effective in other types of AKI.

As definitive treatment for AKI remains elusive; early and accurate AKI detection would provide time to optimize care and mitigate injury. With the adoption of electronic medical records

(EMR), there is tremendous potential although utilizing the large of amount of data in the EMR to effect positive outcomes has not proven to be simple [176]. While a comprehensive discussion of EMR alerts and interventions is beyond the scope of this chapter, it is clear that broad and timely awareness of nephrotoxin exposure and injury is a necessary first step, effective detection systems can be developed, and that the optimal approach is highly dependent on the desired outcome, resource availability, and institutional willingness to accept change management. The use of electronic alerts has been effective when the target of the alert has been front-line providers or an imbedded pharmacist; a positive impact on process outcomes (e.g., reduction of nephrotoxin exposure) has been reported in both smaller pediatric and larger adult studies [177, 178]. It has been more challenging to assess the impact on higher-level patient-related outcomes such as mortality and the need for renal replacement therapy [179–181]. It is clear that highly relevant care recommendations (also referred to as clinical decision support) must accompany any nephrotoxin or AKI-related alert if the notification is to be impactful [182]. Even better than identifying nephrotoxin exposure and nephrotoxic AKI once it develops, is the ability to actually predict exposure and injury. Interest in AKI prediction models has grown substantially over the past decade and many of the earliest models focused specifically on reduction of nephrotoxin-associated AKI [183]. Operational challenges abound but EHR enabled prediction of nephrotoxic AKI remains one of the most promising interventional approaches in theory [176, 184, 185].

One model that has been particularly successful at affecting nephrotoxic AKI is NINJA. Originally a single center program, NINJA was expanded to a multicenter collaborative, which has achieved a reduction in nephrotoxic AKI among hospitalized children receiving noncritical care of nearly 25% [36]. The NINJA model is built on the concept that AKI risk increases with concomitant nephrotoxin exposure and that awareness of this risk has the capacity to modify care and outcomes [186]. NINJA identifies patients receiving a high burden of nephrotoxins and uses this exposure to trigger daily serum creatinine monitoring. The ordering of serum creatinine is multifaceted; it increases awareness of risk, it establishes a protocol to monitor for the adverse event associated with exposure (AKI), and it provides the basis for an injury alert should it occur. Decision support is provided for the duration of exposure, most typically by pharmacists who can recommend alternative therapies. Given its success in noncritically ill children, NINJA has been successfully applied in the neonatal intensive care unit as well [187]. Most recently, the NINJA model was adopted as a pilot program with the safety collaborative Solutions for Patient Safety (SPS), a North American network of >140 pediatric centers. This pilot will attempt to assess the impact of the NINJA bundle across a wide variety of institutions and patient populations.

The future of prediction modeling for nephrotoxin-associated AKI may include a role for renal biomarkers. Again, a complete discussion of biomarkers is beyond the scope of this chapter, but it is likely they will become an integral part of prevention and management strategies in the future. Cellular damage markers such as neutrophil gelatinase-associated lipocalin (NGAL), N-acetyl-β-D-glucosaminidase (NAG), tissue inhibitor of metalloproteinase 2 insulin-like growth factor-binding protein 7 ([TIMP-2]·[IBFBP7]) and kidney injury molecule-1 (KIM-1) have been evaluated in the setting of nephrotoxin exposure [188]. Additional studies are still needed to validate early findings; however, preliminary data are promising [189]. It is likely that biomarkers will be used in conjunction with clinical risk scoring systems or existing clinical interventions such as NINJA to optimize predictive capabilities and effectively reduce nephrotoxic injury [190–192].

Conclusion

In summary, a myriad of nephrotoxin substances exist and while the primary focus in the literature has been on pharmaceutical agents, it is important to remember that naturally occurring compounds and environmenal exposures can cause kidney injury as well. Through various pathophysiologic mechanisms, nephrotoxins may cause glomerular disease, crysalluria, and disruptions of fluid/electrolyte homeostasis; however, the most commonly seen phenotype is AKI. While it is important to understand the nephrotoxic potential of any given agent, it is possible that the concept of a patient's comprehensive nephrotoxin burden is of greater clinical relevance. An understanding of the core concepts that underpin nephrotoxicity allows provider to effectivley manage both exposures and nephrotoxic injury. Although specific intervetions for nephrotoxic AKI do not yet exist, multidisciplinary approaches designed to increase awareness, reduce exposure, and indentify injury have proven quite effective. Over time, novel approaches to identify, prevent, and reverse injury will hopefully reshape our approach to nephrotoxins and nephrotoxic AKI.

Abstract

Progression of chronic kidney disease (CKD) towards kidney replacement therapy is inevitable in some CKD patients and once significant impairment of kidney function has occurred it tends to progress almost irrespectively of the underlying kidney disorder.

In addition to the key players hypertension, proteinuria, and the renin-angiotensin system, other potential contributors such as the underlying kidney disease, age at onset, gender, genetic background, metabolic acidosis, renal anemia, altered mineral homeostasis, dyslipidemia, hyperuricemia, inflammation, and oxidative stress as well as general cardiovascular risk factors such as diabetes, smoking, and obesity also play a role. The current state of knowledge regarding the pathophysiology of kidney disease progression and therapeutic concepts will be discussed in this chapter.

Introduction

Progression of chronic kidney disease (CKD) towards kidney replacement therapy (KRT) is inevitable in some CKD patients and once significant impairment of kidney function has occurred it tends to progress almost irrespectively of the underlying kidney disorder. While the primary disease-causing renal impairment vary, as CKD progresses the mechanisms involved become increasingly similar and ultimately a set of common events contributes to an unstoppable loss of functional nephron mass.

There is clear evidence from clinical studies that both hypertension and proteinuria are key players in the pathophysiology of CKD progression in humans [1–3]. In addition to the renin-angiotensin system other potential contributors, such as the underlying kidney disease, age at onset, gender, genetic background, metabolic acidosis, renal anemia, altered mineral homeostasis, dyslipidemia, hyperuricemia, inflammation, and oxidative stress as well as general cardiovascular risk factors such as diabetes, smoking, and obesity, also play a role.

This chapter summarizes the current state of knowledge regarding pathophysiology of kidney disease progression and therapeutic concepts.

Pattern and Timing of CKD Progression

Several studies have described the pattern of CKD progression in glomerular and non-glomerular pediatric kidney disease.

Data from the prospective, population-based ItalKid Project [4] showed a yearly incidence of KRT of 7.3% with a 68% cumulative risk of KRT by age 20 in children and adolescents with CKD registered in Italy between 1990 and 2000. The loss of renal function was not linear, but was characterized by a greater decline around puberty. The probability of renal survival decreased with lower renal function at baseline.

In a retrospective analysis of 176 patients with renal hypodysplasia from Great Ormond Street Hospital, London, it was suggested that the natural course of kidney function in patients with congenitally reduced kidney mass can be divided into three periods: an initial “hypertrophy” phase characterized by improving kidney function during the first 3 years of life, and a subsequent period of stable kidney function attained by 50% of the patients and lasting for a mean of 8 years, followed by a period of gradually deteriorating kidney function towards KRT [5]. The progression phase started just after infancy in 48% and around puberty in 23% of patients. In 30% kidney function remained stable even beyond puberty. Correlates of deteriorating function were proteinuria, hypertension, urinary tract infections, and lower glomerular filtration rate (GFR) at onset.

In a recent analysis of 4,700 patients with congenital anomalies of the kidneys and the urinary tract (CAKUT) followed in the ERA-EDTA Registry, more than two-thirds of the patients required KRT in adult age, with a mean age at starting KRT of 34 years [6]. These findings support the concept that in patients with a congenital reduction in nephron mass, CKD progression due to ongoing loss of remnant nephrons is a lifelong process.

In a joint analysis of more than 1200 children with glomerular and non-glomerular CKD followed in the CKiD (Chronic Kidney Disease in Children) study and the ESCAPE (Effect of

Strict Blood Pressure Control and ACE Inhibition on Progression of Chronic Renal Failure in Pediatric Patients) trial, children with glomerular disease were estimated to have a 43% shorter time to a composite event of KRT or a 50% GFR reduction or GFR <15 ml/min/1.73 m^2 than children with non-glomerular disease [7]. By staging CKD according to level of GFR and proteinuria, timelines of progression were defined that may guide management strategies in children with CKD. While in children with mild-to-moderate CKD without proteinuria the median time to attainment of the composite endpoint was longer than 10 years, in children within the highest risk group, defined by CKD stage IV and gross proteinuria, 50% of children with non-glomerular CKD reached the composite endpoint within 1.3 years and with glomerular CKD within 0.8 years (Fig. 1).

Renal Physiology of Progressive CKD

Progression of kidney disease can be considered to occur in three phases: First, events related to the initial disease, involving a harmful stimulus and tissue response. Second, conversion from an acute disease state to chronicity and third, a period of progressive decline leading to end-stage kidney disease (ESKD). While in adults the most common causes for CKD are diabetes and hypertension [8], in children the initial insult to the kidney is of a more diverse origin, including CAKUT with hypodysplasia or cystic kidney diseases, metabolic kidney diseases, congenital nephrotic syndrome or acquired glomerulopathies, and hemolytic-uremic syndrome [9].

Although each disorder gives a different pattern of injury, common mechanisms come into play in response to injury. The response of the kidney to a precipitating injury is a critical determinant of outcome. Repair after injury, via both general cellular mechanisms and responses specific to the kidney, may lead to healing or to malfunction and kidney scarring. Basically, the involved repair mechanisms are normal and appropriate attempts to restore nephron function, however, when structural problems or inappropriately balanced responses occur, a state of *misdirected repair* leads to an increase in the loss of function. Physiological responses to the repaired state lead to *adaptation* by the nephron and may result in a new, effective steady state, while excessive responses may lead to abnormal physiology and further cycles of nephron loss and adaptation. Because this leads to long-term deleterious effects in the nephron, such negative responses might be referred to as *maladaptation*.

Primary glomerular injury. Genetic and possibly environmental stimuli lead to podocyte injury resulting in failure of the glomerular filter and proteinuria.

Loss of podocytes permits activation of mesangial and endothelial cells in the glomerular tuft [10]. Likewise, other cell types may contribute to glomerular disease. The initial mesangial location of extracellular matrix (ECM) accumulation in many glomerular diseases suggests that mesangial cells are a primary source of scar tissue [11]. Mesangial cells may also undergo proliferation after a number of stimuli; however, it is not clear whether these mesangial cell responses represent a primary manifestation of injury or a result of misdirected repair. Also, glomerular endothelial cells may proliferate in response to hypertrophic stimuli undergoing phenotypic changes that contribute to scarring [12].

The loss of damaged podocytes may lead to focal and segmental adhesions of the denuded basement membrane of the Bowman capsule, with spreading of the ultrafiltrate into the tubulointerstitial compartment where it causes inflammatory injury (“misdirected filtration”). The remaining nephrons lose their ability to autoregulate glomerular pressure, resulting in transmission of systemic hypertension to the glomerulus. Increased intraglomerular pressure induces proteinuria, which is the pathophysiological link between glomerular, interstitial, and tubular damage.

Tubular injury. Tubular injury and dysfunction may occur secondary to chronic glomerular disease but may also be primary. Chronic tubulointerstitial injury early in life often results from genetic disorders that cause structural disorientation (genetically inherited cystic kidney disease or cystic dysplastic kidney), organellular accumulation of materials that inhibit normal cellular function (cystinosis or Lowe syndrome), or metabolic failure. Other potential causes are obstruction, infections, and toxins, as well as hypoxic/ischemic insults. A common event in the progression of all of these disorders is the occurrence of tubulointerstitial scarring and inflammation, associated loss of nephrons, and their replacement with scar tissue [13].

Tubulointerstitial injury. Renal tubular delivery of biologically active molecules may lead to inflammation and injury to the tubular cells or the tubulointerstitium. In addition, increased distal delivery of filtrate activates the renin-angiotensin-aldosterone system (RAAS) to modify glomerular filtration. This tubulo-glomerular feedback may provide the hypertrophic stimulus described above. In both glomerular and tubulointerstitial disease, cell activation, dedifferentiation, and redifferentiation to a cellular phenotype that mediates attempted repair are stimulated. However, failure of that repair leads to scarring involving *inflammation* and *fibrogenesis,* as is the case in CKD progression.

Inflammation. Progression of focal segmental glomerulosclerosis (FSGS) to ESKD is most strongly associated with inflammatory infiltrates in the tubulointerstitium, suggesting an important role of inflammation in CKD progression.

Macrophages, found both in glomeruli and the tubulointerstitium, exert not only phagocytic function but also synthetic function which is a critical mediator of both repair and scarring. Regulatory cytokines produced by the macrophage include transforming growth factor (TGF)-β, platelet-derived growth factor (PDGF), connective tissue growth factor (CTGF), basic fibroblast growth factor (FGF-2), and tumor necrosis factor (TNF)-α. Macrophages also produce regulators of coagulation and fibrogenesis, complement-related proteins, endothelin-1, and reactive oxygen species. A major determinant of macrophage recruitment is regulatory molecules governing cell adhesion and migration. Injury also activates various other cells in the kidney to express specific chemokines and their receptors playing a role in fibrosis.

Fibrogenesis. In normal tissue, ECM synthesis and degradation are balanced by components regulating ECM protein expression, degradation, and proteolytic enzyme activity. Synthesis of the ECM proteins is regulated at the level of transcription, stimulated by mediators such as TGF-β, and by enzymes that process the ECM proteins both intracellularly and extracellularly to promote ECM incorporation into organized matrices. The maintenance of appropriate balance among the ECM proteins involves both the extracellular matrix proteases such as matrix metalloproteinase (MMP)-2 and urokinase-type plasminogen activator (uPA), and their naturally occurring inhibitors tissue inhibitor of metalloproteinase (TIMP)-2 and plasminogen activator inhibitor (PAI)-1, respectively.

The myofibroblast is the major cellular contributor to fibrogenesis by very high synthetic capacity and production of large amounts of ECM. It has been hypothesized that myofibroblasts are derived from other cells in the kidney by the process of epithelial-to-mesenchymal transition (EMT). However, even kidney cells that do not undergo EMT may still contribute to progression by producing chemoattractants, procoagulants, and profibrotic factors. In addition, delivery of large amounts of plasma to the tubular lumen increases exposure of the luminal side of the tubule to cytokines and growth factors, which could also stimulate cells to undergo EMT and produce additional mediators.

Role of the renin-angiotensin-aldosterone system (RAAS) in CKD progression. Angiotensin II (Ang II)*,* the primary effector of the RAAS, is mechanistically involved in most of the processes described above. Renin release from the juxtaglomerular cells drives systemic Ang II generation. Most of the intrarenal effects of Ang II are mediated via the angiotensin (AT)1 receptor. Ang II is a potent vasoconstrictor that augments intraglomerular pressure by increasing the efferent arteriolar tone. Furthermore, Ang II increases intracellular calcium in podocytes inducing cytoskeletal changes and altered podocyte function with induction of protein ultrafiltration, the proliferation of smooth muscle cells, and the glomerular and tubular expression of various growth factors, cytokines, and chemokines. Ang II also stimulates *oxidative stress*, which perpetuates the upregulation of cytokines, adhesion molecules, and chemo-attractants. Finally, intrarenal Ang II stimulates neuronal afferences which are assumed to activate central nervous structures regulating the sympathetic tone. Hence, Ang II is pathophysiologically involved in the state of sympathetic hyperactivation that is characteristic for CKD and represents another important mechanism for renal disease progression and cardiovascular morbidity.

In patients with reduced nephron mass and anemia, hypoxia of tubular cells is additionally favored by an increased oxygen consumption by tubular cells of the remaining nephrons, a decreased number of interstitial capillaries and accumulation of extracellular matrix. Conversely, hypoxia stimulates fibrosis and enhances the local production of reactive oxygen species. Oxidative stress also induces the release of pro-inflammatory and pro-fibrotic molecules, thereby enhancing the production of extracellular matrix by fibroblasts favoring tubular cell death (Fig. 2).

Nephron hypertrophy. With a decrease in renal mass, renal blood flow perfuses fewer nephrons with consequently increased single-nephron plasma flow and GFR. Hyperperfusion and hyperfiltration may stretch the nephron, which can induce hypertrophic and hyperplastic signaling with increased activity of the RAAS.

Chronic nephron loss. Glomerular sclerosis, tubulointerstitial fibrosis, and tubular atrophy result in a further loss of functioning renal mass, closing a vicious circle by further increasing intraglomerular pressure and hypertrophy of the remaining glomeruli.

Risk Factors for CKD Progression

Nonmodifiable Risk Factors

Underlying Kidney Disease and Genetic Disposition

A major determinant of rates and patterns of progression is the primary etiology of the underlying kidney disease [14]. The most common causes of CKD and KRT in children are diseases related to CAKUT [4, 14, 15], followed by glomerular disease, neurogenic bladder, and other disorders. In children, hypodysplasia accounts for 57.5% of CKD patients, but only 39.6% of those with KRT [4], while patients with underlying chronic glomerulonephritis or FSGS comprise 4.4% of CKD but 10.7% of KRT patients. These results suggest that patients with glomerular lesions progress more rapidly to KRT [6, 16].

The progression phenotype may be linked to an *underlying genetic defect*. In disease entities caused by defects in more than one gene, progression patterns may differ according to the gene involved. Even within the same gene, the localization and type of the causative mutations may be a key determinant of the renal prognosis.

Additionally, common *polymorphic variants* in various genes encoding cytokines, growth factors, and regulatory peptides may determine an individual's susceptibility for renal injury, renal disease progression, and the response to renoprotective treatment.

Recent and ongoing meta-analyses of genome-wide association studies (GWAS) are aiming to identify loci associated with incident CKD or the risk of ESKD in general population-based cohorts, as well as in adult and pediatric CKD cohorts. For instance, common risk variants of genes related to nephrogenesis (*ALMS1, VEGFA,* and *DACH*), in glomerular filtration barrier formation and podocyte function (*DAB2, PARD3B,* and *VEGFA*), angiogenesis

(*VEGFA*), and to renal function (*UMOD, SHROOM3,* and *STC1*) have been identified [17–19]. Genome-wide association studies may also allow identification of variants related to known risk factors for CKD progression as hypertension, proteinuria, or anemia in adults as well as children [20].

Age at Attainment of Renal Mass Deficit

The age at which a significant loss of kidney mass occurs may influence the degree of glomerular hypertrophy and the long-term prognosis for kidney survival. Patients born with unilateral renal agenesis or multicystic dysplastic kidney are at greater risk for proteinuria, hypertension, and loss of kidney function than subjects after loss of one kidney in later life due to an accident or after kidney donation, suggesting that the number of functional nephrons in congenital solitary kidneys might be decreased [21].

Fetal Programming

Fetal programming describes a process by which changes to the intrauterine environment increase the susceptibility of a fetus to diseases later in life. Fetal programming induces epigenetic changes that are modified postnatally and may have direct consequences on kidney development and function. It has been shown by Barker and colleagues that low birth weight is correlated with the incidence of cardiovascular disease in later adulthood [22]. Subsequent studies have suggested that low nephron number predisposes to adult hypertension and there is a clear correlation of low birth weight with decreased kidney mass and nephron number [23]. A recent study in more than 400 Japanese children born with very low birth weight showed a significant contribution of intrauterine malnutrition to chronic kidney damage [24]. Vice versa, higher estimated weights in utero at birth and at 6 months postgestational age are associated with higher kidney volume and higher GFR at age 6–7 years [25]. Although an association between low nephron number and subsequent hypertension or kidney dysfunction is difficult to demonstrate directly, clinical evidence at least suggests such an association.

Growth

In some kidney diseases, the likelihood of CKD progressing to kidney failure is greatest in the first year of life or around the adolescent growth spurt [5], i.e., periods of accelerated overall growth. This led to the hypothesis that somatic growth in the absence of equivalent kidney growth may be a cause of CKD progression due to a relative decrease in the available nephron mass related to body weight. This may again implicate low nephron number as a key risk factor in CKD progression.

Major Modifiable Risk Factors in CKD

Hypertension

Hypertension is not only a well-known cause of kidney failure and a marker of the severity of the underlying kidney disease, but also an independent risk factor for kidney disease progression in adults [1–3].

Hypertension prevalence estimates in children with CKD range from 20% to 80%, depending on the degree of kidney dysfunction and underlying kidney disease. However, even children with CKD stage 2 or renal hypodysplasia, conditions usually not strongly associated with hypertension, may present with elevated blood pressure (BP) [26]. A systolic BP greater than 120 mmHg has been associated with a faster GFR decline in a large prospective study of children with CKD [27]. In a retrospective cohort study of more than 40,000 adult patients included in a hypertension disease registry, systolic BP was associated with incident CKD. Above a systolic BP level of 120 mmHg, each 10 mmHg increase in baseline and time-varying systolic BP was associated with a 6% increase in the risk of developing CKD. Every 10 mmHg increase in systolic BP was associated with an additional 0.2 ml/min/1.73 m^2 decline in eGFR per year [28].

Among CKD children included in the CKiD study, time-varying BP measurements $\geq$ 90th percentile compared to $<$ 50th percentile were associated with a hazard odds ratio of 3.75 in non-glomerular and of 5.96 in glomerular disease of attaining the composite end point of 50% GFR reduction from baseline, or GFR <15 ml/min/1.73m^2, or dialysis or transplant [29].

Independent of the absolute BP level, alterations of the physiological circadian BP variation with attenuation of the nocturnal fall of BP ("dipping" pattern) are associated with an increased cardiovascular risk and a more rapid progression of kidney failure in adult CKD patients [30]. With respect to the comparative importance of absolute nighttime BP values over nondipping status on the prognosis of renal outcomes, nighttime BP demonstrated a better association with both renal outcomes and markers of kidney dysfunction. However, increased nighttime BP and nondipping status usually coexist, and consequently their relative significance might be synergistic, additive, or even indifferent in diverse clinical settings [31].

Proteinuria

Population-based studies in healthy individuals have demonstrated that proteinuria is an independent risk factor for ESKD and overall mortality [32, 33]. In adults with diabetic and nondiabetic kidney disorders, proteinuria is clearly predictive of the renal prognosis [34, 35]. In the Ramipril Efficacy in Nephropathy (REIN) trial [36], urinary protein excretion was the only baseline variable correlated with GFR decline and progression to ESKD. Although the spectrum of underlying kidney disorders in children markedly differs from adults, the "European Study Group for Nutritional Treatment of Chronic Renal Failure in Childhood" first demonstrated in 200 children with CKD stage 3–4 that even in pediatric kidney disease, proteinuria and hypertension are major predictors of GFR decline [27]. The finding that proteinuria predicts kidney disease progression has been confirmed in children with hypodysplastic kidneys by the ITALKID Project [37]. In the CKiD study, a decrease in GFR was associated with an increase in proteinuria [38], and baseline proteinuria and systolic BP levels were independently associated with CKD progression in children with non-glomerular CKD [39]. In the ESCAPE trial, baseline proteinuria and residual proteinuria during ACE inhibition were quantitatively associated with renal failure progression [40, 41].

Additional Contributing Factor

Among children with moderate CKD, ***dyslipidemia*** is common and associated with lower GFR, nephrotic range proteinuria, and non-renal factors including age and obesity [42]. Epidemiological studies give some evidence that dyslipidemia is an independent risk factor not only for cardiovascular disease (CVD) but also for progressive chronic renal failure [43]. The dyslipidemic pattern differs between the major renal disease entities [44] and the degree of dyslipidemia parallels the degree of renal function impairment. Underlying mechanisms of uremic dyslipidemia include insulin resistance [45], obesity, hyperparathyroidism [46], malnutrition, acidosis [47], and impaired catabolism of triglyceride-rich lipoproteins by decreased activity of lipoprotein lipase and hepatic triglyceride lipase.

In addition, there are observations that the insulin resistance syndrome may underlie or mediate the association between lipids and loss of renal function. In humans, a strong relationship between the ***metabolic syndrome*** and the risk for CKD and microalbuminuria was found in a large nondiabetic general population [48].

As adipose tissue generates high levels of circulating free fatty acids (FFA) and FFA uptake and oxidation in CKD are reduced by hypoadiponectinemia, leptin resistance, and increased cytokine release from adipose tissue and macrophages, intracellular FFA accumulates [49]. This may cause mesangial and epithelial cell injury and renal disease progression as a consequence of FFA-induced lipotoxicity. However, the evidence for dyslipidemia as an independent risk factor for renal disease development and/or progression is not as strong in clinical studies as it is in experimental settings.

In adults, ***obesity*** predisposes to diabetic nephropathy and appears to be a negative prognostic factor also in other nephropathies and an independent risk factor for accelerated progression [50]. These effects could relate to the relative ratio of body mass to nephron mass, since weight loss intervention reduces hyperfiltration and proteinuria, but also could relate to other effects on BP and metabolism. A meta-analysis indicated that obesity poses a significant risk for CKD or its exacerbation, both independently and in interaction with other factors. The severity of the risk increases with increasing BMI [51].

In CKD, impaired excretion of ammonia, reduced tubular bicarbonate reabsorption, and insufficient renal bicarbonate production in relation to the amount of acids synthesized by the body and ingested with food lead to acidification and may contribute to an activation of the complement pathway that contributes to inflammation and progressive nephron loss. Studies in adult CKD patients suggest that ***metabolic acidosis*** is associated with faster decline in eGFR [52]. In the Cardiovascular Comorbidity in Children with CKD Study (4C Study), pediatric patients with CKD stage 3–5 with time-varying serum bicarbonate below 18 mmol/l had a significantly higher risk of CKD progression compared to those with a serum bicarbonate of 22 mmol/l or more [53].

Serum uric acid is often elevated in CKD subjects due to decreased renal clearance. Serum uric acid is an independent risk factor for kidney disease in healthy adults, with high levels predictive of decline in GFR. Uric acid levels tend to be higher in obese patients, and obesity is a risk factor for CKD as well [54]. Because impaired renal function may decrease the ability to excrete uric acid, it is difficult to know whether the association of ***hyperuricemia*** with more rapid progression is causal. A single, high uric acid determination was not predictive of kidney failure in the Modification of Diet in Renal Disease (MDRD) study [55]. However, data from the CKiD study indicated that hyperuricemia may be an independent risk factor for faster progression of CKD in children and adolescents [56].

In patients at advanced stages of CKD, increased ***oxidative stress*** is associated with additional complications such as hypertension, atherosclerosis, inflammation, and anemia. Because oxidative stress is implicated in the CKD pathophysiology, as the kidney function deteriorates, the redox status imbalance becomes more profound [57].

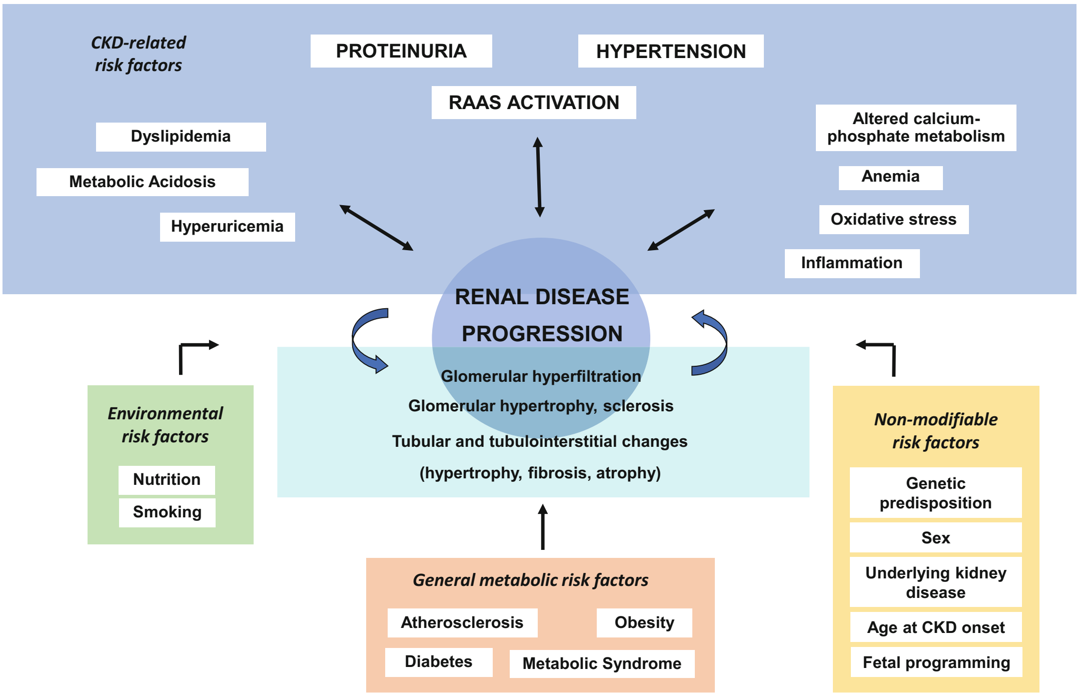
Disturbances of the ***bone mineral metabolism*** also may influence CKD progression. Elevated serum alkaline phosphatase and low 25-hydroxyvitamin D levels are risk factors associated with progression. Phosphorus accumulation is caused by loss of nephron mass, but is also an independent risk factor for progression in adults and children [15]. These observations may be related to the role of phosphate accumulation in stimulating fibroblast growth factor 23 (FGF23) [58], which has been identified as an independent risk factor for progression in adults and children. Because CKD-associated mineral and bone disease is a result of decreased renal function, it is difficult to distinguish between cause and effect in progressive loss of renal function. It is likely that both are present; loss of function stimulates FGF23 expression and activity, which induces further progression mechanisms.

In CKD patients, potentially harmful effects of the degree of exposure to ***smoking*** on the progression of CKD have been shown. In the KoreaN Cohort Study for Outcomes in Patients with Chronic Kidney Disease (KNOW-CKD study), smoking was associated with a significantly increased risk of renal disease progression in smokers compared with never-smokers [59]. Similar results were found for children exposed to secondhand smoking. In the CKiD cohort, exposure to secondhand smoke was independently associated with nephrotic range proteinuria, and may be an important factor to consider in CKD progression [60].

The most relevant risk factors for CKD progression are summarized in Fig. 3.

Nephroprotective Treatment Strategies

Based on the current understanding of the mechanisms of kidney disease progression, several nephroprotective strategies have emerged in recent years, mainly based on clinical evidence established in adult patients, but a growing body of evidence supports their efficacy in children too. Approaches to treatment could involve some combination of treating the underlying disease, controlling systemic and intrarenal BP and proteinuria, regulating the fibrogenic and inflammatory response, and addressing the metabolic consequences of progressive kidney disease (Fig. 4).



CKD-related risk factors
PROTEINURIA
HYPERTENSION
RAAS ACTIVATION
Dyslipidemia
Metabolic Acidosis
Hyperuricemia
Altered calcium-phosphate metabolism
Anemia
Oxidative stress
Inflammation
RENAL DISEASE PROGRESSION
Glomerular hyperfiltration
Glomerular hypertrophy, sclerosis
Tubular and tubulointerstitial changes
(hypertrophy, fibrosis, atrophy)
Environmental risk factors
Nutrition
Smoking
Non-modifiable risk factors
Genetic predisposition
Sex
Underlying kidney disease
Age at CKD onset
Fetal programming
General metabolic risk factors
Atherosclerosis
Obesity
Diabetes
Metabolic Syndrome

Treatment of the Underlying Disease

Treatment of the underlying kidney disease remains the optimal approach, although patients often present at a time when irreversible damage has already occurred due to maladaptive repair processes and the resulting fibrosis. However, specific treatment in defined disease entities, for example, complement blockade in C3 complement disorders may prevent further injury and ameliorate CKD progression.

BP Control

In children with CKD, the BP level is correlated with the rate of GFR decline and vice versa; there seems to be an almost linear relationship between BP level achieved by antihypertensive treatment and the rate of kidney failure progression [61]. This relationship appears to persist well into the normal range of BP [34, 62]. Thus, it has been postulated that intensified BP control, aiming for a BP goal in the lower-normal range, might be nephroprotective in CKD patients. However, while several studies in adults have provided proof to the concept that consequent antihypertensive therapy slows down the rate of progression [61], interventional trials comparing different BP targets yielded somewhat conflicting results: A kidney survival benefit of intensified BP control was demonstrated by the MDRD trial in adults with proteinuria and CKD. Patients with proteinuria randomly assigned to a low BP goal (mean arterial pressure <92 mmHg) exhibited improved renal survival after 4 years of follow-up, whereas nonproteinuric patients had no benefit [63]. Extended follow-up for >10 years could demonstrate a persistently reduced renal risk in the low BP group [62].

Nevertheless, this could not be shown in other studies in adult populations [64–66]. In the Ramipril Efficacy In Nephropathy (REIN)-2 extension trial in nondiabetic adults with proteinuria and CKD, a BP target of <130/80 mmHg vs. a diastolic target of <90 mmHg did not result in improvement of renal survival [66]. In the African American Study of Kidney Disease and Hypertension (AASK) trial in >1,000 African Americans with hypertensive nephrosclerosis, randomization to either ramipril, metoprolol, or amlodipine (targeting at mean arterial pressure of 102–107 vs. <90 mmHg) did not affect the rate of GFR loss within 3–6 years [64]. However, intensified BP control exerted a nephroprotective effect during the follow-up period in patients with significant baseline proteinuria and ACE inhibitor treatment [67]. In the Appropriate Blood Pressure Control in Diabetes (ABCD) trial, a low BP target did not improve overall renal survival in hypertensive patients, whereas normotensive patients seemed to have some benefit from lowering BP level to the low-normal range [65]. These partially discrepant findings may be explained by methodological and population differences between studies. Indeed, in a systematic review and meta-analysis including 11 trials providing information on almost 9300 CKD patients, a more intensive BP-lowering strategy reduced the risk of CKD progression and end-stage kidney disease compared to standard BP control. Subgroup analysis showed effect modification by baseline proteinuria; intensive BP lowering was not effective to reduce the risk of kidney failure in patients without proteinuria at baseline [68].

In children with CKD, the ESCAPE trial provided evidence that in children on angiotensin-converting enzyme inhibitors (ACEI) intensified BP control targeting for a 24-h mean arterial pressure below the 50th percentile provides superior long-term nephroprotection compared to a higher target range (50th to 95th percentile) [40]. Despite a relatively modest additional reduction of BP level by around 3–4 mmHg, kidney survival was markedly improved by the intensified intervention protocol. Within 5 years of observation, the risk of losing 50% eGFR or progressing to end-stage kidney disease was 41.7% in the conventional treatment arm compared to 29.9% in the ***strict BP control*** arm [40]. Intensified BP control was effective in children with underlying glomerulopathy as well as renal dysplasia or hypodysplasia, albeit not in other congenital or hereditary nephropathies. Strict BP control was tolerated very well in the vast majority of children.

In view of the results of the ESCAPE trial, the most recent pediatric guidelines published by the European Society of Hypertension have recommended a BP target (for casual BP and for ambulatory BP monitoring) below the 75th percentile in nonproteinuric children with CKD, and below the 50th percentile in those with proteinuria [69]. The AAP Clinical Practice Guideline for Screening and Management of High BP in Children and Adolescents, published in 2017, recommended a BP goal below the 50th percentile for all CKD children [70].

Until publication of the SPRINT (Systolic Blood Pressure Intervention Trial) results [71], most guidelines for BP targets in adult patients with CKD favored treatment to a BP <140/90 mm Hg, with consideration of a lower target of <130/80 mm Hg for those with more severe proteinuria. Because in patients with stage 3 to 4 CKD-intensive BP management seemed to provide the same benefits for reduction in cardiovascular outcome and all-cause mortality as were seen in the full study cohort, a lower target of <130/80 mm Hg for all adults with CKD is now recommended in the USA [72]. The latest European Hypertension Guideline [73] recommends a systolic target BP of 130 to 140 mmHg. Further details on BP management in children is discussed in ▶ Chaps. 62, “Pathophysiology and Epidemiology of Hypertension in Children,” and ▶ 63, “Evaluation and Management of Hypertension in Children.”

Proteinuria Control

Proteinuria is not only a mere marker of progressive CKD but also plays an important causal role in pathogenesis of CKD. This is in line with the finding in interventional trials that reduction of proteinuria is associated with a slowing of GFR loss in the long term [34, 64, 74, 75]. For example, in the MDRD trial, for each 1 g/day reduction in proteinuria observed after 4 months of antiproteinuric therapy (i.e., BP and dietary interventions), the subsequent GFR decline was slowed by about 1 ml/min per year [34]. The goal of antiproteinuric treatment is to reduce proteinuria as much as possible, ideally to <300 mg/m^2/day. This degree of proteinuria reduction appears to be associated with the maximal renoprotective effect [76, 77]. In the ESCAPE trial, ramipril therapy lowered proteinuria by a mean of 44%. Higher proteinuria at baseline was independently associated with a larger proteinuria reduction [41]. In the CKiD cohort, proteinuria was lower in glomerulonephritis patients on RAAS blockers compared to patients who were not on RAAS blockade [38].

In addition, it has been shown, for instance in the MDRD study [34], the ABCD study [78], and the AASK trial [64], that BP control lowered proteinuria. A low BP goal, i.e., <125/75 mm Hg in adults, either reduced proteinuria absolutely by 50% [34] or prevented the two- to threefold increase in proteinuria observed in patients with the more “conventional” BP goal of 140/90 mm Hg [78]. For MDRD study patients with proteinuria >3 g/day, post hoc analysis indicated benefit from treatment to a lower BP goal (<130/80 mm Hg); however, this was related to kidney outcomes only [34].

Many studies of antihypertensive therapy, mostly by ACEI or angiotensin receptor blockade (ARB), suggest that the effect is greatest in patients with high-grade proteinuria [68, 79, 80].

In the ESCAPE trial baseline and residual proteinuria during ACE inhibition was quantitatively associated with kidney failure progression [40, 41]. In addition, the early antiproteinuric effect of ACE inhibition was associated with long-term preservation of renal function. Thus, proteinuria lowering should be considered an important target in the management of pediatric CKD [41]. Of note, whereas the excellent antihypertensive effect of the ACEi treatment and its impact on progression persisted during the ESCAPE trial study period, proteinuria gradually increased again over time, resulting in a level of proteinuria after 36 months that did not differ significantly from that at baseline [40].

With respect to the findings given above, efficient control of BP and minimization of proteinuria are still the two most important measures to preserve residual kidney function.

Additional Nephroprotective Treatment Options

While the different classes of antihypertensive agents are comparable with respect to their BP lowering efficacy, they differ significantly in terms of their effects on proteinuria and CKD progression [64, 75, 81, 82].

By virtue of their pharmacological properties drugs antagonizing the RAAS, i.e., ACEi and ARB, are pharmacotherapeutics of first choice in both adults and children with chronic kidney disease.

RAAS antagonists suppress angiotensin II synthesis (ACEi) or action (ARB). This results in a reduction of intraglomerular pressure and proteinuria, diminished local release of TGF-ß and other growth factors, cytokines and chemokines, with consequently attenuated glomerular hypertrophy and sclerosis, tubulointerstitial inflammation, and fibrosis as well as in a normalized central nervous sympathetic tone by reduced renal afferent nerve stimulation.

Several randomized trials in adults with diabetic or nondiabetic kidney disease have demonstrated a more effective reduction of proteinuria, usually by 30–40%, by ACEi as compared to placebo and/or other antihypertensive agents. In the long term, this was associated with a reduced rate of renal failure progression [74, 76, 80, 83, 84].

ACEis and ARBs are comparable regarding their renoprotective properties. However, the superiority of RAAS antagonists is related to the prevailing degree of proteinuria. Insufficient high dosing of RAAS antagonists may fail to achieve effective RAAS suppression at the kidney tissue level and maximum antiproteinuric and nephroprotective effects. In addition, some patients may develop partial secondary resistance to ACE inhibition or RAAS blockade [85] by compensatory upregulation of ACE-independent angiotensin II production. While the maximal antiproteinuric effects of RAAS antagonists occur at doses exceeding those providing maximal antihypertensive action, regulatory authority approval is usually available only for the indication of hypertension in the respective dose range. Therefore, it is generally recommended to administer these drugs, after confirming tolerability, at their highest approved doses.

The specific effects of RAAS antagonists on glomerular perfusion and intraglomerular pressure induce an immediate drop in the GFR, usually by approximately 10–15% at initiation of treatment. The antiproteinuric response within the first 2–3 months of administration appears predictive of the long-term renoprotective effect [41, 86] and may be utilized to adjust the appropriate drug dose. In patients with CKD, the reduction of intraglomerular pressure may cause a significant increase in serum creatinine, which might be considered a positive predictor of the long-term renoprotective effect [87]. Acute renal failure after administration of a RAAS antagonist is a rare event and usually related to concomitant volume depletion. Thus, in episodes of acute dehydration RAAS antagonists should be temporarily discontinued and hydration ensured to prevent acute kidney injury. Furthermore, in girls who might become pregnant, the teratogenicity of RAAS blockade should be considered and effective contraception has to be provided.

The finding that discontinuation of RAAS inhibitors in children with CKD is associated with an acceleration of kidney function decline, even in advanced CKD [88], underscores the importance of RAAS inhibition in the protection of kidney function.

Dual RAAS blockade using an ACEi and ARB combination therapy has only a minor effect on BP (3–4 mmHg) compared to monotherapy, but increases the antiproteinuric effect by 30–40% [89, 90]. However, findings of the ONTARGET trial in adult populations with high cardiovascular risk did not support dual therapy with telmisartan and ramipril over monotherapy in patients with low GFR or albuminuria [91, 92]. Although combination therapy reduced proteinuria to a greater extent than monotherapy, it had no additional cardiovascular benefit and led to a higher incidence of life-threatening adverse events including acute kidney failure and hyperkalemia, resulting in worse major renal outcomes (chronic dialysis or doubling of serum creatinine). However, it is questionable whether these findings, derived from an adult high-risk population with diabetes and established cardiovascular disease, can be extrapolated to patient cohorts at lower cardiovascular risk [93], for example, pediatric CKD patients.

Mineralocorticoid receptor antagonists (MRA) also act by RAAS suppression resulting in BP lowering. While the use of *spironolactone* is limited by its endocrine side effects, *eplerenone* has minimal affinity for progesterone and androgen receptors and apart from the risk of hyperkalemia, reported side effects were similar to placebo [94]. However, a recent Cochrane review concluded that the effects of aldosterone antagonists when added to ACEi or ARB (or both) on the risks of death, major cardiovascular events, and kidney failure in patients with proteinuric CKD are uncertain. MRA may increase the risk of hyperkalemia, acute kidney injury, and gynecomastia when added to ACEi and/or ARB [95].

In contrast, *finerenone*, a structurally different, nonsteroidal, selective MRA, has been shown in animal studies to block inflammation and fibrosis in both the heart and kidneys with only small effects on serum potassium. In the Fidelio-DKD trial involving adult patients with CKD and type 2 diabetes, treatment with finerenone resulted in lower risks of CKD progression and cardiovascular events than placebo [96]. The simultaneous use of oral potassium absorbers, binding potassium in the gastrointestinal tract, may improve tolerability of MRA in patients with increased risk for hyperkalemia.

The ***renin-antagonist*** *aliskiren*, blocking the conversion from angiotensinogen to angiotensin I, has also been shown to effectively reduce BP to a similar extend as ARBs and a combination therapy of aliskiren and valsartan at maximum recommended doses provided significantly higher reductions in BP than did monotherapy [97]. However, due to the higher risk of cardiovascular complications found in the ALTITUDE study, the combination therapy of aliskiren with ACEi or ARBs in patients with diabetes or reduced renal function is not recommended.

Calcium channel blockers (CCBs) can achieve BP control in CKD patients; however, CCBs of the dihydropyridine type (amlodipine and nifedipine) failed to reduce progression of chronic renal failure. Dihydropyridine CCBs may even induce or aggravate proteinuria and more rapid CKD progression [75] and should be avoided in patients with proteinuria unless in combination with RAAS antagonists [98].

β-blockers have been shown to be also effective in lowering BP in CKD patients. Metoprolol and atenolol demonstrated beneficial effects on the decline of renal function in CKD patients [99] and in the AASK trial metoprolol had an antiproteinuric effect almost comparable to ramipril [64]. Newer β-blockers such as carvedilol have even improved antiproteinuric effects, probably due to sympathicoplegic effects.

Because hypertension is a multifactorial disorder, monotherapy is often not effective in controlling BP and proteinuria. In the ESCAPE trial one-third of patients required ***antihypertensive combination therapy*** to attain a BP level in the normal range. For those patients with a target BP in the lower normal range (<50th percentile) antihypertensive combination therapy had to be prescribed in almost 40%. This is in line with findings from the CKiD study where 35% of patient had combination therapy at baseline [100].

In CKD patients, RAAS antagonists are most commonly combined with a diuretic or with a calcium channel blocker, whereas their combination with a β-blocker usually does not exert an additive effect on BP control.

In view of the fact that nocturnal BP non-dipping is an independent risk factor for CKD progression, ***antihypertensive chronotherapy***, i.e., the timing of antihypertensive drug dosing, may be relevant. While antihypertensive “chronotherapy” has not been demonstrated to affect CKD progression as yet, in a study randomly assigning hypertensive CKD patients either to take all prescribed antihypertensive medications in the morning or to take at least one of them at bedtime, bedtime dosing was associated with improved BP control and significant reduction of cardiovascular risk [101].

Over the last decade, several drugs developed to improve glucose control in patients with type 2 diabetes mellitus (T2DM), such as metformin, glucagon-like peptide 1 (GLP-1) agonists, dipeptidyl peptide 4 (DPP-4) antagonists, and ***sodium glucose cotransporter 2 (SGLT2) inhibitors,*** have been shown to exert advantageous cardiorenal effects. Among these substances, SGLT2 inhibitors (gliflozins) are the most promising drug class. Apart from the glucose lowering effects, SGLT2 inhibitors also decrease BP, body weight, and albuminuria. Large clinical outcome trials with the SGLT2 inhibitors dapagliflozin, canagliflozin, or empagliflozin in T2DM have demonstrated potent long-term renoprotective effects of SGLT2 inhibition, including reductions of 30–50% in albuminuria or proteinuria and clear beneficial effects on hard renal outcomes such as doubling of serum creatinine, eGFR decline, attainment of KRT, or death due to renal disease [102, 103]. These nephroprotective effects are based on a decrease of sodium delivery to the distal tubule and reduced glomerular blood flow leading to reversal of glomerular hypertension and hyperfiltration [104].

Prevention of CKD Progression by Optimized CKD Treatment

Treatment of uremic dyslipidemia may be another component of renoprotective therapy. General measures in the prevention of dyslipidemia in CKD patients include prevention or treatment of malnutrition, correction of metabolic acidosis [47], hyperparathyroidism [46], and anemia [105], all of which may contribute to dyslipidemia. Although, as for the general population, therapeutic life style modification (diet, exercise, and weight reduction) is recommended for adults and children with CKD-related dyslipidemia by the KDIGO Clinical Practice Guideline for Lipid Management in Chronic Kidney Disease [106], the ***lipid-lowering*** effect of these interventions in CKD patients is usually not impressive. Thus, in adults with CKD stage 3–5 and hypercholesterolemia, either aged $>$ 50 years or aged 18–50 years plus increased cardiovascular risk treatment with a statin or statin/ezetimibe combination is recommended. However, in children treatment of CKD-related hypercholesterolemia is not recommended and treatment for hypertriglyceridemia should focus on severe cases due to lack of clear benefits compounded by safety concerns associated with long-term use in children [106].

With respect to renoprotection, experimental evidence suggests that statins may retard renal disease progression not only by their lipid lowering, but also by lipid-independent pleiotropic effects. Data from a meta-analysis including 10 studies on the impact of statin therapy on CKD progression add evidence that statin use in CKD patients may delay progression, but may have a dose-related effect on kidney function as only high-intensity statin therapy significantly improved renal function assessed by estimated GFR [107].

Also, the degree of CKD and proteinuria may influence the effect of statin therapy on CKD progression. A study in almost 3500 CKD patients demonstrated statistically significant effects on GFR decline in adults with CKD stage 3b to 5 or proteinuria $>$ 1000 mg/day, while no significant effects were seen in mild-to-moderate CKD and nonproteinuric patients [108].

No studies have evaluated the usefulness of statins in CKD children to date.

Observational studies report independent associations between ***serum phosphate level, PTH, FGF-23, klotho, and vitamin*** D and the risk of renal disease progression, cardiovascular disease, and mortality; this is discussed further in ▶ Chap. 72, “Chronic Kidney Disease – Mineral and Bone Disorder (CKD-MBD).”

In animal models, vitamin D (paricalcitol) effectively attenuates renal interstitial fibrosis through a combination of inhibitory actions on the RAAS, inflammation, and epithelial/mesenchymal transition [109]. In children with CKD, 25(OH)D levels $>$50 nmol/L were associated with better preservation of renal function, even in the presence of concomitant ACEi therapy [110].

In this context, a PTH-independent beneficial effect of **phosphate restriction** on kidney disease progression has been suggested by animal studies. The finding that dietary phosphorus restriction may stabilize kidney function has been also confirmed by several studies in adults with CKD [63]. Additionally, calcium-free phosphate binders may have superior reno- and cardioprotective advantages in patients with CKD. For instance, sevelamer has been proven to have a lower all-cause mortality in patients with CKD stage 3 to 5D compared to calcium-based phosphate binders [111].

Metabolic acidosis is common in patients with CKD and may contribute to the development and worsening of proteinuria and tubulointerstitial fibrosis. In a randomized controlled trial evaluating the renoprotective potential of oral bicarbonate supplementation in adult patients with CKD [112], CKD progression rate was reduced to 1 ml/min/year in patients with serum bicarbonate levels ≥22 mmol/L compared to >2.5 ml/min/year in patients with uncorrected low bicarbonate levels. Similarly, data from the 4C Study provide evidence that children with time-varying serum bicarbonate under 18 mmol/l have a significantly higher risk of CKD progression compared to those with a serum bicarbonate of 22 or more mmol/l [53]. Thus, control of metabolic acidosis may be an important component of renoprotective therapy in patients with progressive CKD.

Another factor in progressive CKD is serum ***uric acid***. Allopurinol treatment improved renal outcome in CKD patients, compared to placebo, without a change in BP level [113] and Febuxostat treatment has been shown to slow down kidney disease progression [114]. However, the CKD-FIX trial could not demonstrate a beneficial effect of uric acid lowering on kidney disease progression in stage 3–4 CKD patients [115].

Much attention has been focused on the effect of ***dietary protein restriction*** on progression. Based on prior animal studies, the MDRD study sought to determine whether less than 0.6 g/kg/day protein intake would delay the onset of KRT. Although early results suggested some benefit [116], a systematic analysis by the Cochrane Group identified only two adequate studies of dietary protein intake and did not find a beneficial effect of this treatment [117]. In children reduced protein intake to the maximal acceptable lower limit did not slow down renal progression [27]. Further reductions may be effective but not acceptable for patients. Furthermore, therapeutic strategies of protein reduction in children may be conflicting, since a low-protein diet carries the risk of low-calorie intake, while a high-calorie intake is needed for optimal growth. Therefore, a low-protein diet is not recommended.

Other Potential Treatment Options

While RAAS antagonists exert indirect anti-inflammatory and antifibrotic properties via blockade of RAAS-dependent profibrotic and inflammatory pathways as outlined above, other nonspecific ***anti-inflammatory and antifibrotic drugs*** may decrease fibrogenesis by reducing macrophage infiltration and subsequent recruitment of fibroblasts or generation of reactive oxygen species. For example, pirfenidone, exerting antifibrotic, antioxidant, and anti-inflammatory properties, interfering with the expression, secretion, and the effect of TGF-β, improved kidney function and proteinuria and reduced kidney scarring in animal models; however, in clinical trials in FSGS or diabetic nephropathy patients, pirfenidone showed conflicting results failing to prevent proteinuria or GFR decline particularly in patients with renal dysfunction [118, 119].

Activation of ET_A receptor mediates inflammation, fibrosis, and proteinuria, while ***endothelin A receptor antagonists*** (ERAs) have been shown to reduce albuminuria and BP, but also to cause sodium retention and anemia. A large randomized controlled trial in patients with T2DM and CKD using the fairly unselective endothelin receptor antagonist avosentan was terminated early because of an increased frequency of heart failure with avosentan [120]. Atrasentan, a more selective endothelin receptor antagonist, reduced the risk of renal events compared with placebo in preselected patients with diabetes and CKD. These data support a potential role for selective endothelin receptor antagonists in protecting renal function at least in patients with T2DM at high risk of developing ESKD [121]. Combined ET_A and angiotensin II blockade by sparsentan, a drug comprising moieties of irbesartan and atrasentan in one molecule, has been shown to be effective in patients with primary FSGS in achieving significantly greater reductions in proteinuria compared to irbesartan [122].

Pentoxifylline (PTF), a nonspecific phosphodiesterase inhibitor, shows anti-inflammatory, antiproliferative, and antifibrotic properties. Small clinical trials evaluating PTF in patients with CKD reported conflicting data. A meta-analysis of studies on PTF in combination with ACEi or ARB treatment provided evidence that combination therapy may lead to a greater reduction in proteinuria and attenuate the decline in eGFR in patients with stages 3–5 CKD [123]. Of note, the existing data suggest that patients with proteinuria may have better protection from PTF treatment than nonproteinuric patients.

Neprilysin (neutral endeopeptidase or membrane metallo-endopeptidase) degrades numerous peptide hormones, among others bradykinin, endothelin, ANP, and BNP. ***Neprilysin inhibition*** (NEPi) may be a therapeutic strategy that enhances the activity of the natriuretic peptide system inducing natriuresis, diuresis, and inhibition of the renin-angiotensin system and the sympathetic nervous system. Sacubitril/valsartan, the first angiotensin receptor-neprilysin inhibitor (ARNI), has been shown to substantially improve not only cardiovascular outcomes in adults with heart failure but also to delay CKD progression in this population. Although ARNIs have not shown similar effects on kidney function in the short-to-medium term in CKD patients, treatment was associated with substantial reductions in cardiac biomarkers and in BP [124].

Conclusions

In children with congenital or acquired kidney diseases progression towards KRT is common and once a significant impairment of kidney function has occurred progression continues irrespectively of the underlying kidney disease. Timing of onset of CKD and progression rate in defined disease entities may be influenced by genetic factors. Hypertension and proteinuria are the most important independent risk factors for renal disease progression. Therefore, therapeutic strategies to prevent progression should target BP control and reduction of proteinuria. Blockade of the RAAS exerts not only BP lowering but also antiproteinuric and anti-inflammatory effects, thus attenuating renal disease progression. Furthermore, intensified BP control exerts additional renoprotective effects in pediatric CKD.

Other important factors contributing to renal disease progression comprise mainly the secondary complications of CKD, such as metabolic acidosis, anemia, dyslipidemia, hyperuricemia, and vitamin D deficiency. Thus, optimal treatment of CKD-associated disorders is key in preventing CKD progression.

Abstract

The global burden of chronic kidney disease remains high, and the cost of caring for patients with CKD is substantial, especially if end-stage kidney disease occurs. The incidence and prevalence of chronic kidney disease is understudied in children, and most of our data and current understanding are derived from large national registries of children receiving kidney replacement therapy. We have made significant progress in identifying risk factors that lead to the progression of chronic kidney disease in children, which has led to improved outcomes for children who require kidney replacement therapy. However, not all children have access to dialysis and kidney transplantation when end-stage kidney disease occurs depending on where they live in the world. Understanding the epidemiology of chronic kidney disease in children remains critical for the early recognition and prevention of the progression of chronic kidney disease and achieving equity in outcomes globally.

Introduction

As of 2017, approximately 9% of the world's population is estimated to have chronic kidney disease (CKD), and the global burden of disease remains high [1]. The cost of caring for patients with CKD remains substantial, and some developing countries do not have the resources to provide kidney replacement therapy (KRT) to those in need. While CKD is a major cause of morbidity and mortality [2], the prevalence of CKD remains understudied in certain areas of the world and in children. Much of our current understanding of the epidemiology of CKD in children is extrapolated from large national registries of children receiving KRT [3–5], as few countries routinely screen healthy children for the presence of CKD [6]. As a consequence, limited data are available surrounding the prevalence of CKD in children.

Despite advances in the care of children with CKD over the past 30 years, a small proportion of children with CKD still progress to end-stage kidney disease (ESKD) and require KRT during childhood [2]. The onset of ESKD is particularly devastating for children, as ESKD can have substantial adverse effects on growth, psychosocial and emotional well-being, educational attainment, and patient-centered outcomes including quality of life [7]. Understanding the epidemiology of CKD in children is critical for the early identification and detection of disease and delivery of interventions to either prevent or slow the progression of CKD. In addition, knowledge of the presence of CKD allows for the timely preparation of affected children and their families for KRT.

Definition of CKD in Children and Measurement of Kidney Function

According to the Kidney Disease Improving Global Outcomes (KDIGO), CKD in children $\geq$2 years of age is defined as either [1] presence of an glomerular filtration rate (GFR) <60 mL/min/1.73 m^2 for at least 3 months or [2] presence of structural damage or markers of reduced kidney function, such as proteinuria, albuminuria, or histologic abnormalities even when the GFR is $\geq$60 mL/min/1.73 m^2 [8]. However, in children under 2 years of age whose GFR is still undergoing expected physiological increases to adult levels, this definition of CKD is not applicable. Normative age-specific reference ranges for serum creatinine values in children under 2 years of age are available [9]. The degree of impairment in kidney function in children under 2 years of age can be determined based on the number of standard deviations that any serum creatinine value is below the mean value that is expected for age.

In children, the GFR can be estimated using the revised (bedside) Schwartz equation, which is computed as 0.413*serum creatinine/height (in cm) [10]. The bedside Schwartz equation is currently the most commonly used creatinine-based equation for the estimation of GFR in clinical practice. The bedside Schwartz equation has been validated in various pediatric populations across a wide range of kidney function, although validation studies in children with very low kidney function (e.g., GFR < 15 mL/min/1.73 m^2) are limited [11, 12]. Other equations are also available for the estimation of kidney function in children [13, 14].

For young adults, some studies have suggested that using a mean of the values obtained from the bedside Schwartz equation and CKD-EPI creatinine-based equation (which has been validated in adults) improves the accuracy of the estimation of kidney function [15, 16].

Because creatinine is influenced by muscle mass and children with CKD may have low muscle mass and growth impairment, biomarkers that are not influenced by muscle mass such as cystatin C may also be useful for the estimation of kidney function. Equations to estimate kidney function using cystatin C alone or cystatin C in conjunction with serum creatinine are available and have been validated in children [17, 18]. Because these equations require the incorporation of sex, height, cystatin C, and blood urea nitrogen, their use may be less practical than the bedside Schwartz equation, and cystatin C assays may not be available in all parts of the world.

CKD is classified into stages of severity based on the level of GFR and proteinuria in children in the same approach as in adults. Currently, KDIGO guidelines recommend the consideration of albuminuria for staging of the severity of CKD, as adult studies have shown that presence of albuminuria is highly predictive of progression of CKD, and albuminuria measurements can be standardized and more precisely measured at lower ranges than proteinuria [8, 19, 20]. In children, proteinuria (often expressed as a urine protein-to-creatinine ratio) is more often used as a marker of CKD progression, as some etiologies of CKD in children do not necessarily lead to albuminuria but can cause non-albuminuric proteinuria. In children, proteinuria has been shown to have similar prognostic implications as albuminuria, and reduction of proteinuria is associated with better kidney survival as observed in adults [21–23]. A recently developed equation that converts proteinuria to albuminuria is available [24], but has yet to be externally validated.

Incidence and Prevalence of CKD

Screening for CKD remains a matter of controversy, and most countries no longer perform routine screening for the presence of CKD except in Asia [25, 26]. Spain estimated the incidence of CKD stages 2–5 in children was approximately 9 per million children per year and prevalence was 71 per million children per year [27]. In a study in England, the incidence and prevalence of children was similar to that reported in Spain but increased over time to 25 and 105 per million children per year, respectively [28].

In a recent study from National Health and Nutrition Examination Survey in the US, between 3–4% of the screened adolescent population had albuminuria, and $< 1\%$ had low eGFR that could potentially be consistent with presence of CKD stage 3, although confirmation of abnormal eGFR was not performed in this study [29]. However, these rates are consistent with the prevalence of low eGFR and albuminuria reported in children in population-based studies from China and Turkey [30, 31]. International variations in the incidence of CKD and its prevalence are shown in Fig. 1.

A recent study of Israeli adolescents and young adults who had a health screening exam prior to their compulsory military service between 1967 and 1997 and who reported a history of congenital abnormalities of the kidney and urinary tract (CAKUT), glomerulonephritis, or pyelonephritis were more likely to develop ESKD during

adulthood, and their ESKD onset was at a young age during 30-years of follow-up [32]. The higher risk of ESKD in these Israeli individuals was noted despite the presence of normal serum creatinine, blood pressure, and absence of dipstick proteinuria at the time of their health screening exam [32].

In a similar study, presence of persistent and asymptomatic hematuria in Israeli adolescents and young adults was associated with a higher albeit small absolute risk of ESKD onset during later adulthood [33]. These data suggest that a small proportion of the general population of children could have asymptomatic CKD that could be diagnosed earlier if mass screening were to be implemented, but no studies have shown that early detection of asymptomatic disease would improve long-term outcomes.

Incidence and Prevalence of ESKD in Children

Data on pediatric ESKD requiring KRT (dialysis or kidney transplantation) are more robust due to the availability of national or international registries, at least in developed countries in Europe, Australia and New Zealand, and the USA. However, in some countries, access to KRT for children remains limited, and the vast majority of children receiving KRT are those residing in developed countries [34].

The incidence of ESKD in children varies widely across different countries but ranges from 5 to 10 per million children per year among patients under 20 years (Fig. 2) [5, 35, 36]. The incidence of ESKD in Japan is slightly lower than that reported in other nations, whereas the incidence in the USA is higher than that reported in other nations [37, 38]. The incidence of ESKD varies by race (higher in Blacks, Aborigines, and Southeast Asians compared with Caucasian children) [39] and age (children <5 years of age and adolescents have higher incidence). [38, 40] The incidence of ESKD has remained stable in some nations but is declining in the US [38].

The prevalence of ESKD in children varies between 40 and 60 per million children in Europe and Australia [41, 42], with the prevalence being higher in the USA (around 100 per million children) and lower in Brazil [38]. This prevalence has remained relatively stable in most nations since the 2000s (Fig. 2b).

Etiology of CKD and ESKD in Children

The etiology of CKD in children differs from that observed in adult populations, where diabetes and hypertension remain the leading causes of kidney disease. In children, CAKUT account for 50–60% of CKD in children, followed by glomerular diseases (5–15%) and hereditary conditions (10–20%) [5]. More recently, the lower cost and enhanced capacity to perform whole exome sequencing in children with CKD has led to increased recognition of genetic (and specifically monogenic) causes of CKD, which is now thought to account for 20% of all CKD prior to the age of 25 years [43]. However, the classification of different etiologies of CKD (such as the exact definition of CAKUT) can vary across different studies, which may lead to variations in the reported prevalence of the different causes of CKD.

Of note, the prevalence of different causes of CKD varies substantially by ethnicity and geographic location [3, 28, 44–46, 48, 49]. For example, congenital nephrotic syndrome of the Finnish type is the leading cause of pediatric ESKD in Finland but is a rare cause of ESKD in other nations. In addition, presence of two high-risk variants of *APOL1* genotype (which is more common in the Black population due to the protection conferred by two high-risk variants of *APOL1* against trypanosomiasis) may contribute to a higher prevalence of CKD in children in certain parts of the African continent and in the Black population [49]. High-risk *APOL1* genotype has been associated with glomerular disease (especially focal segmental glomerulosclerosis) and HIV-associated nephropathy in children [50, 51].

In low- and middle-income countries that do not have national registries, estimating the most common causes of CKD is significantly more challenging and based primarily on single-center data [52–55]. Endemic causes of CKD in certain parts of the world such as Central America (Meso-American nephropathy) or Sri Lanka may be an important cause of CKD in children and young adults, though the lack of routine screening and performance of kidney biopsies may complicate the ability to obtain accurate estimates of the prevalence of such etiologies of CKD in children [56, 57].

Among children who develop ESKD, the prevalence of various etiologies of kidney disease

Fig. 2 (**a**) Incidence of KRT per million children (pmc) of the same age. Data of pediatric patients aged 0–19 years except USA (0–21 years) and United Kingdom (0–15 years). Incidence rates of 2018 except Brazil (2012), Israel (2017), Malaysia (2015), Russia (2017), Taiwan (1998–2009), Tunisia (2017), and USA (2016). Incidence rates of dialysis only for Argentina, Brazil, Israel, Japan, and Singapore. (**b**) Prevalence of KRT per million children (pmc) of the same age. Data of pediatric patients aged 0–19 years except USA (0–21 years) and United Kingdom (0–15 years). Prevalence rates as of December 31, 2018 except Brazil (2012), Guatemala (2016), Malaysia (2015), Russia (2017), Tunisia (2017), and USA (2016). Prevalence rates of dialysis only for Argentina, Brazil, Guatemala, Japan, Singapore, and Turkey

differs from that observed in children with CKD. CAKUT and glomerular diseases remain the most common causes of kidney disease in the pediatric ESKD population, but the prevalence of CAKUT as a cause of ESKD is lower than for CKD and ranges from 25–35% in most reported studies due to the slower progression of non-glomerular diseases towards ESKD [38, 58].

Kidney Replacement Therapy Modalities

Approximately 20% of children start KRT with pre-emptive transplantation in Europe and the United States, although the rates of pre-emptive transplantation vary by race and geographic location [59–61]. In some countries, kidney transplantation is not available as an option for children [34]. Children who do not receive pre-emptive kidney transplantation may receive peritoneal dialysis or hemodialysis, but the prevalence of the use of each of these modalities varies substantially depending on the country, reimbursement system for ESKD care, and public policies [62, 63]. The most common modality in most countries is hemodialysis, although in younger children less than 5 years of age, peritoneal dialysis is a more prevalent treatment modality.

In terms of prevalence of treatment modalities for ESKD, kidney transplantation is by far the most common treatment modality in industrialized nations, though disparities in access to kidney transplantation and living donors do exist by race, sex, and across different nations [64–66]. Differences between countries, particularly in Europe, have been attributed to factors such as whether pediatric priority is considered in the organ allocation system, acceptance of and practices related to deceased organ donation, availability of living donors, and payor and public policies surrounding kidney transplantation [64, 67].

Epidemiology Surrounding Risk Factors for the Progression of CKD and CKD Management

The progression of CKD varies substantially depending on the etiology of CKD, the severity of kidney impairment, and the presence of additional modifiable or non-modifiable risk factors or genetic susceptibility. Data from one US cohort of children suggested that the progression rate to ESKD was 17% at 1 year and 39% at 3 years, and median time to progression to ESKD was 4.5 years in a cohort of 4000 children with stage 2–4 CKD [68]. However, the rate of progression to ESKD varies substantially based on the presence or absence of additional risk factors, most importantly of which are the level of kidney function and degree of proteinuria [69].

Non-modifiable Risk Factors for the Progression of CKD to ESKD

There are multiple risk factors for the progression of CKD in children that are not readily modifiable. First, the etiology of CKD is important, as children with glomerular diseases have been shown to have faster progression of disease compared to children with non-glomerular etiologies of CKD [70]. For children of Black race, the presence of two variants of *APOL1* genotype has been associated with faster progression of CKD [50–52, 71]. Although presence of two high-risk variants of *APOL1* is strongly associated with progression of disease, to date, no specific therapeutic interventions have been shown to delay the progression of CKD in such individuals.

Preterm birth and low birth weight have also been associated with onset of faster eGFR decline or development of kidney disease, which in part may be due to lower nephron mass [72–75]. Some children may have genetic loci of susceptibility to the progression of CKD [76]. Parental literacy has been identified as a risk factor for progression of CKD in children [77]. While in adults, low socioeconomic status has also been a predictor of progression of CKD, in children, this relationship has not been as strongly established. In one study, annual household income was not associated with progression of CKD in children [78].

Modifiable Risk Factors for the Progression of CKD to ESKD

Proteinuria is one of the strongest risk factors for the progression of CKD in adults and children [22, 23, 70, 79]. Suppression of proteinuria by an angiotensin-converting enzyme inhibitor was strongly predictive of kidney survival in participants of the ESCAPE trial [23]. These data align closely with data from adults with CKD, in whom suppression of proteinuria is also a target for slowing the progression of CKD, especially in adults with diabetes [8]. In general, use of renin-angiotensin-aldosterone system blockade is recommended in order to reduce proteinuria in children and adults with CKD.

There is a high prevalence of masked hypertension in children with CKD which has been associated with target organ damage [80], and routine ambulatory BP monitoring on a regular basis is recommended for the initial diagnosis of hypertension and to ensure adequate BP control in children. One of the only randomized controlled trials in children with CKD, the ESCAPE trial demonstrated that intensive lowering of ambulatory blood pressure below the 50th percentile mean arterial pressure for age was associated with slower progression of CKD to KRT over 5 years of trial follow-up [81]. This has led KDIGO guidelines to recommend intensive lowering of ambulatory BP to <50th percentile [82]. However, targets for clinic BP treatment in children with CKD remain a subject of debate, as the correlation between ambulatory and clinic BP is not well established.

Some studies have suggested that obesity is a risk factor for the development of ESKD in children as in adults [83, 84]. Although failure to thrive can occur in children with CKD, a growing prevalence of obesity has been noted in children starting ESKD [85, 86]. In one study of more than one million Israeli young adults undergoing military health screening exam, elevated BMI (meeting criteria for overweight or obese) was associated with a higher risk of diabetic and non-diabetic ESKD during long-term follow-up, although the overall absolute incidence of ESKD was very low in this cohort [84]. Few longitudinal studies have examined whether changes in weight (or weight modification) can alter the rate of progression of CKD. In one observational study, weight loss (but not weight gain) was associated with higher risk of onset of the need for KRT than maintenance of stable weight [87]. Obesity in children starting KRT has been associated with a substantially higher risk of mortality during long-term follow-up [86].

Anemia is common in children with CKD and likely multi-factorial [88]. The presence of anemia in children with CKD has been associated with a more rapid decline in kidney function as well as an increased risk for hospitalization [89, 90]. Currently, higher hemoglobin targets are recommended in children with CKD or ESKD compared with recommended targets in adults, as these higher targets have not been associated with adverse cardiovascular events or death as observed in adults [91, 92].

Finally, presence of metabolic acidosis, hyperuricemia, and low serum albumin are additional risk factors that have been associated with progression of CKD in children [68, 95, 96, 98, 99].

The management of specific risk factors that may help delay the progression of CKD are reviewed in subsequent chapters. An overview of the management of CKD risk factors is shown below in Table 1.

Table 1 Overview of the treatment of select risk factors to delay the progression of kidney disease

Risk Factor	Recommendation
Hypertension	Lower blood pressure to <50th percentile ambulatory mean arterial pressure
Proteinuria	Use of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers to achieve suppression of proteinuria
Metabolic acidosis	Treatment with alkali to maintain bicarbonate levels >22 meq/L
Anemia	Target hemoglobin is 11–12 g/dL in children Treat iron deficiency if present Treat with erythropoietin-stimulating agents
Weight	Maintenance of normal weight status is recommended Collaboration with a dietician to ensure adequate caloric intake is recommended
Height	Maintenance of normal height is recommended Correction of anemia, metabolic acidosis, and abnormalities in bone mineral disease

Predicting the Risk of Progression of CKD

In recent years, although there has been a trend towards earlier initiation of dialysis in both adults and children, this has not been associated with better outcomes in children starting KRT [97]. There has been recent interest in prediction models that can better guide clinicians in appropriately timing discussions surrounding KRT and preparation of children and their families for such. In adults, the Kidney Failure Risk Equations were developed for the prediction of a 2- and 5-year risk of progression to KRT and were validated in a large multi-national cohort with high risk discrimination [98]. The Kidney Failure Risk Equations were also validated in a cohort of children with CKD and found to have similar high risk discrimination [98, 99]. This calculator's advantages include its simplicity, as only four variables (age, sex, eGFR, and proteinuria) are needed to estimate the risk of developing ESKD over defined periods of time. A second risk prediction model was recently developed in children with CKD and provides an estimate of the time to progression to KRT [69]. This calculator incorporates cause of ESKD, kidney function, and proteinuria to provide estimates of the remaining time before the need for KRT arises.

In addition, novel biomarkers for the progression of CKD in children have been identifies. For example, plasma soluble urokinase plasminogen activator receptor (SUPAR) has been shown to be a biomarker of CKD progression, even after accounting for kidney function [100, 101]. However, whether treatment should be modified in relationship to SUPAR levels remain unclear. Fibroblast growth factor-23 which is a key player in abnormal mineral bone metabolism pathways in CKD has also been identified as an independent predictor of CKD progression, though whether FGF-23 is a therapeutic target remains unclear [93].

Complications of CKD

Various complications of CKD are discussed at length in the relevant chapters. A brief overview is provided here.

Cardiovascular Disease

The life expectancy of a child who develops ESKD is substantially shorter than that in the general population without ESKD [102]. Young adults treated with dialysis have mortality rates that are more than 100-fold higher compared with their healthy age-matched peers [103]. The leading cause of death among children and adults with ESKD has been attributed to cardiovascular disease (CVD), and in particular, sudden cardiac death [104, 105].

Children with CKD are likely to have many traditional cardiovascular risk factors, including hypertension and dyslipidemia [106, 107]. However, children with CKD and ESKD may also share many non-traditional risk factors for cardiovascular disease, including volume overload, inflammation, and abnormalities of parameters in the bone mineral metabolism [108–110]. There is ample data to suggest that children with CKD have subclinical cardiovascular disease. Elevated carotid intimal thickness and pulse wave velocity have been noted in children with CKD [111]. As CKD progresses, the prevalence of left ventricular hypertrophy has also been shown to increase [111, 112]. While the absolute rate of atherosclerotic events remains low in children [113], adolescent and young adults with ESKD are both at risk for hospitalization for cardiovascular-related complications [103].

Growth

Many children with childhood-onset CKD will have short stature, which is likely related to a number of nutritional and metabolic factors including anemia, uremia, metabolic acidosis, derangements in calcium, phosphorus, parathyroid hormone, and hormonal disturbances [111, 115]. Growth failure has been associated with a higher risk of hospitalizations and mortality in children with ESKD [116, 117].

The clinical management of growth retardation in children with CKD includes correction of metabolic derangements including acidosis and mineral and bone disorder and careful attention to the adequacy of nutrition [118]. Recombinant human growth hormone (GH) is a treatment option, though under-utilization of GH is common and GH may not be available in all countries [119]. Height gain and GH use have been associated with higher physical and social functioning as reported by children and parents, but the need for daily injections may increase the likelihood of nonadherence to therapy [120].

Mineral Bone Disease

Abnormalities in calcium and phosphorus homeostasis and parathyroid hormone are also common in children with CKD, with elevated serum phosphorus and low calcium often observed starting in stage 4–5 CKD. Dietary modification is the first-line treatment for such abnormalities. Phosphate binders and vitamin D supplementation are mainstays of therapy in order to normalize mineral and bone disorder parameters, which are important for growth and bone health [121]. Such abnormalities should be corrected prior to the consideration of GH therapy. Although normalization of calcium and phosphate parameters can be achieved, treatment has not been consistently associated with improved survival. Fractures have been reported in 16% of children with CKD in one US cohort [122].

Neuro-Cognition

Children with CKD are at increased risk for neurocognitive deficits compared to their healthy peers. CKD-related factors that may contribute to neurocognitive changes of CKD include anemia, hypertension, uremia, and cardiovascular disease. In general, children with CKD have been observed to have mild deficits in academic skills, memory, visual motor performance, and executive function, with such deficits being worse in children treated with dialysis than with CKD [123–125]. Younger age of CKD onset and longer duration of disease have been associated with lower IQ and greater severity of neuro-cognitive deficits [126, 127].

Quality of Life

Life participation, survival, kidney function, and infection are some of the most important concerns for children and adolescents with CKD or ESKD and their families. Children with CKD have reported poorer overall quality of life compared to healthy children, including lower physical, emotional, and social functioning [128]. Similar poor quality of life has been reported in children and adolescents receiving KRT [129]. Not only does CKD affect the child, but families have also reported significant stressors, including inability of parents to maintain employment, psychological fatigue, and inability of parents to balance their personal needs with the needs of their child with chronic illness, and financial stressors related to the care of a child with CKD [130–132].

Transition of Children with CKD or ESKD into Adulthood

Adolescents are at higher risk for complications related to CKD, as self-management of CKD or ESKD and non-adherence to therapy is frequently present during this tumultuous period. Non-adherence in children with CKD has been reported to range from 4% to 22% [133]. In one study, patients 14–16 years old were reported to have the highest rates of graft loss among all patients $\leq$55 years old [134]. Children who survive to adulthood with KRT have reported lower physical functioning and quality of life and are less likely to be employed, have started families, and have high-income jobs [135].

Careful attention to the transition of children with CKD or children receiving KRT into adult healthcare systems is recommended in order to prevent poor outcomes during this period [127].

Mortality in Children with ESKD

The mortality of children with ESKD has declined over the past few decades in both children treated with dialysis and transplant [2, 4, 136], but the risk of death in children with ESKD remains 30 times higher than that of the general population of the same age [137]. The mortality rate in children with ESKD is about 50–60 deaths per 1000 patient-years (ranging from 15 to 100) [2, 4] depending on age and treatment modality, with mortality risk being highest in those receiving hemodialysis, followed by peritoneal dialysis, and lowest in those with a functioning allograft. The excess mortality attributable to ESKD has been declining over time in children, with the decline being most prominent in young children receiving KRT and with a functioning transplant [138]. Thus, kidney transplantation remains the treatment modality of choice in children, although this is not an option in all nations. The risk of mortality varies substantially across different countries; rates of discontinuation of dialysis and death are high in Africa [139].

The most common cause of death in children treated with KRT are cardiovascular causes in about 35% of patients, followed by infections [104, 113]. Of the cardiovascular causes of death, sudden cardiac death is significantly more common than traditional atherosclerotic disease as the cause of death in those who started KRT as children [113]. Risk factors for death in children treated with KRT include younger age at initiation, female sex, Black race/ethnicity, and late referral to pediatric nephrology care [4, 35, 140–143] .

Conclusion

Although our knowledge of epidemiological data surrounding CKD and ESKD in children has increased substantially over the last few decades, most of the available data rely on national registries and limited data are available on the incidence and prevalence of CKD in children. Standardization of the classification of CKD has helped to streamline research and clinical care for children with CKD. Given the general low prevalence of CKD in children (compared with adults), additional multi-national collaborations are needed to better define the scope of the disease and areas where improvements can be made to prevent the onset of KRT and improve survival in the pediatric population.

Abstract

Normal growth and development are central goals in the management of children with chronic kidney disease (CKD). Nutritional adequacy plays an influential role in the achievement of these goals. This chapter will review the growth patterns observed in children with CKD as well as the causes of growth impairment and the signs and causes of protein energy wasting (PEW) in pediatric CKD. The methods for assessing growth and nutritional status, along with the limitations of these measures in CKD, will also be reviewed. Management strategies to optimize growth and nutrition among children with CKD, including the use of recombinant growth hormone, will be outlined. Finally, the chapter will conclude with information pertaining to the neurodevelopment of the child with CKD.

Introduction

Normal growth and development are central goals in the management of children with chronic kidney disease (CKD). Nutritional adequacy plays an influential role in the achievement of these goals. This chapter will review the growth patterns observed in children with CKD as well as the causes of growth impairment and the signs and causes of protein energy wasting (PEW) in pediatric CKD. The methods for assessing growth and nutritional status, along with the limitations of these measures in CKD, will also be reviewed. Management strategies to optimize growth and nutrition among children with CKD, including the use of recombinant growth hormone, will be outlined. Finally, the chapter will conclude with information pertaining to the neurodevelopment of the child with CKD.

Normal Growth and Development

Normal Phases of Growth Normal growth can be divided into three phases – infancy, childhood, and puberty. Each phase is primarily influenced by a different factor [1–3]. The *infancy phase* of growth, a continuation of fetal growth, is driven primarily by nutrition. Nutritional intake stimulates insulin and insulin-like growth factors, the major regulators of growth in this phase. Linear growth and weight gain are most rapid in the first 2–3 months of life, showing rapid deceleration thereafter [2]. At 6–12 months of age, the early, nutrition-dominated infancy phase of growth is replaced by the *childhood phase* of growth. Growth hormone is the major driver of growth in the *childhood* phase, during which growth velocity decelerates over time [3]. In the childhood phase, growth rates of ~7–8 cm/year are typical at 3 years of age and of ~6–7 cm/year at 10 years of age. The onset of puberty marks the beginning of the *pubertal phase* of growth, influenced mainly by sex hormones [1–4]. Pubertal growth patterns differ for girls and boys. Girls experience a major increase in growth velocity during the first 2 years of puberty, followed by an additional

2–3 years of slower growth. In contrast, boys show a smaller increase in growth velocity in early puberty, and some may even experience a decline in growth velocity for 12–18 months in early puberty before the growth spurt in mid-puberty. Like in girls, the growth spurt lasts about 2 years and is followed by 2–3 additional years of gradual growth.

Normal Puberty There is substantial variation in the age of onset of puberty in healthy children. Puberty typically begins earlier in girls than in boys, and sexual development is also completed at a younger age in girls than boys. Sexual development is assessed using Tanner staging [5]. For girls, breast and pubic hair development are staged separately. For boys, genital (testicular volume and penile size) and pubic hair development are staged separately. Pubic hair and breast (girls)/genital (boys) staging may be discordant. In boys, testicular volume should be measured using a Prader orchiometer; a testicular volume of 4 ml signals the onset of puberty [6].

Sexual development is considered to be delayed in a girl if there is no breast development by 14 years, if there is more than a 5-year interval between breast development and menarche, or no menarche by 16 years. In boys, the absence of testicular enlargement by 14 years or an interval of more than 5 years between onset and completion of genital development indicates delayed sexual maturation [7].

Growth and Development in Chronic Kidney Disease

Growth disturbance is one of the hallmarks of CKD in childhood [8]. Short stature is common among children with CKD, with younger age of onset, and more advanced CKD associated with larger height deficits. Short stature has long been recognized as a complication of CKD, with 30–50% of individuals with childhood onset CKD being reported as having height deficits as adults [9]. CKD affects each of the phases of growth in a slightly different way.

Growth failure has clinical, social, and mental health implications for children with CKD. There is a significant association between growth failure and increased mortality and morbidity in children with end-stage kidney disease (ESKD). Wong et al. assessed the association between anthropometric measurements and mortality among 1,949 children with ESKD. In this group, the risk of death was 14% higher for every 1 unit increment in height standard deviation score (SDS) [10]. Furth reported that among pediatric patients with ESKD, those with moderate/severe growth failure at the beginning of dialysis had a higher likelihood of hospitalization and death than those with normal stature, after adjustment for relevant covariables [11]. Although growth failure has been reported as a risk factor for adverse clinical outcomes in children with CKD, it has not been independently related with the decline of GFR in the Chronic Kidney Disease in Children (CKiD) cohort study [12]. Nevertheless, growth failure has been associated with a 40% shorter time to deterioration of kidney function after transplantation compared to pediatric kidney transplant recipients with normal stature [13].

There are also significant psychological consequences of growth failure associated with CKD in children. Children with growth failure demonstrate higher rates of poorer school performance and lower self-esteem compared to children with expected height [14]. Al-Uzri and colleagues investigated 483 patients and/or parents recruited in the CKiD study who had completed the Pediatric Quality of Life (QoL) Inventory on at least two visits. They reported that a 1 unit higher height z-score was associated with a seven point higher PedsQL parent-proxy score assessment of physical/social functioning of their children. Interestingly, height is associated with QoL over the entire age spectrum [15]. Among adults who had pediatric onset of CKD, those who achieved a greater final adult height have described a better QoL [16]. Therefore, one of the central goals in treating children with CKD is early intervention to maximize growth and developmental potential.

Disruption of Normal Phases of Growth in CKD During the infancy phase of growth, poor nutritional intake may result in growth restriction. In addition, the childhood phase of growth may be delayed in onset until 2–3 years of age in about 40% of boys and 27% of girls with CKD; 60% of both boys and girls may show a transient resumption of the infancy pattern of growth after starting the childhood phase [4]. Because linear growth is quite slow at the end of the infancy phase and faster at the onset of the childhood phase, delayed onset of the childhood phase or return to the infancy phase will result in overall slower growth than normal.

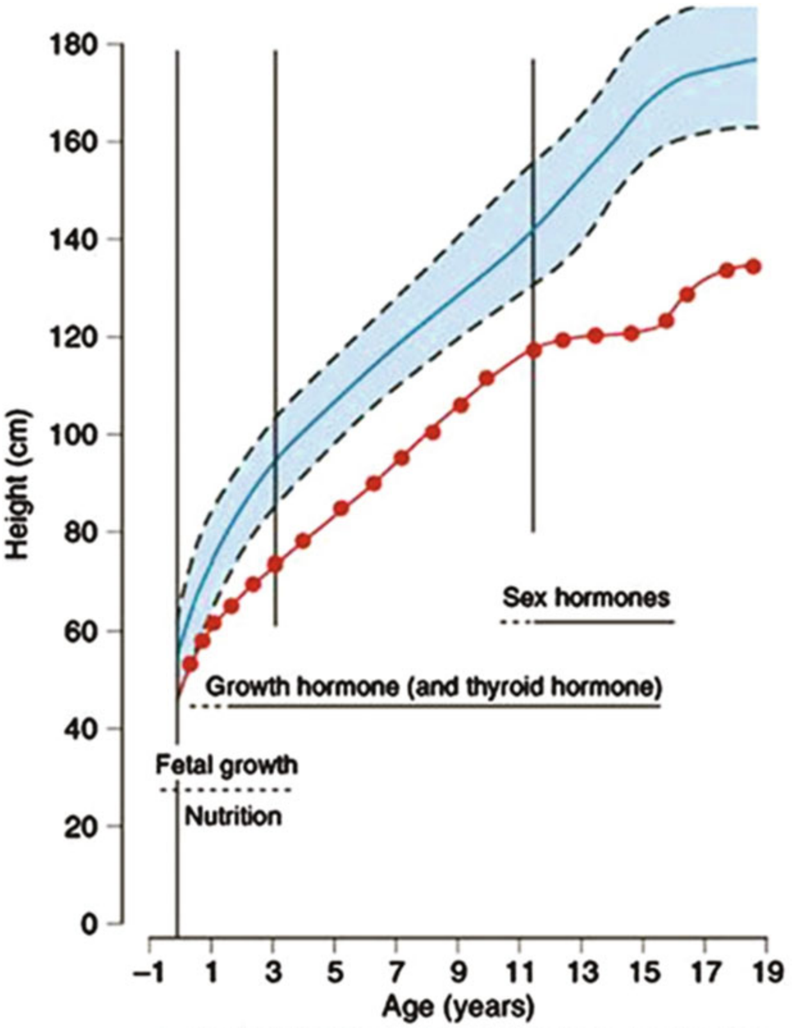
Children with CKD growing in the childhood phase may have normal growth velocity. However, children with a lower glomerular filtration rate (GFR) have significantly lower growth velocity than children with a higher GFR [17]. In addition, the onset of pubertal growth is delayed among children with CKD, and the pubertal growth spurt is shorter [18]. The typical growth pattern for a child with CKD is illustrated in Fig. 1 [19]. It should be noted, however, that most of these observations were made more than 20 years ago and more recent data reveal that even in pre-pubertal patients requiring kidney replacement therapy, pubertal onset may be normal or only slightly delayed [20, 21].

Together, the disturbances in the normal pattern of growth that are characteristic of CKD may lead to severe short stature. Children with CKD from a very young age are particularly severely affected; failure to grow at a normal rate during critical periods when growth is normally rapid is very difficult to correct later.

Pubertal Development in CKD In healthy children, gonadotropin-releasing hormone (GnRH) stimulates the release of luteinizing hormone (LH) in pulsatile nocturnal bursts from the pituitary gland. In CKD, GnRH secretion may be blunted, resulting in a decreased frequency of LH pulses [22]. Although LH levels may be increased in CKD due to decreased renal clearance, pubertal patients receiving maintenance dialysis produce substantially less LH overnight than healthy peers [23]. As a result of these abnormalities, the onset of puberty may be delayed in children with CKD. However, both boys and girls with CKD do eventually progress through the normal stages of puberty and attain full sexual maturation. Because growth and pubertal development are so tightly linked, it is important that pubertal development be carefully monitored in conjunction with growth assessment.

Etiology of Growth Impairment in CKD There are a variety of reasons that children with CKD experience impaired growth. As noted above, poor caloric intake – common among infants with CKD – has the most important effect on growth in the first 1–3 years of life. Anorexia appears to be the primary reason for growth failure in infants and very young children with CKD, and has been observed in infants with glomerular filtration rates as high as 70 ml/min/1.73 m^2 [24]. A variety of factors may cause anorexia in CKD, including disturbances in the appetite-regulating hormones leptin and ghrelin, altered taste, gastroesophageal reflux and frequent emesis, delayed gastric emptying, and elevated levels of cytokines such as IL-1, IL-6, and tumor necrosis factor (TNF)-α [25]. Although some older children may have poor energy intake, this is not common; most older children have normal energy intake relative to body size [8]. Developmental abnormalities and/or psychological factors may also contribute to poor intake. In addition, children with a history of anorexia may have poor oral-motor skills, resulting in very slow eating and low intake. The struggles around eating between parents and anorectic children, and the use of nasogastric tubes, may ultimately result in negative psychological reactions to food and further food refusal [26].

A large proportion of children with CKD have poor urinary concentrating ability and therefore high urine volumes. Such children often feel thirsty and prefer to drink water over milk or other fluids. The volume of water taken may be large enough to diminish their appetite for milk or food. Children with CKD may also experience salt wasting, resulting in chronic volume depletion and impaired growth. Uncorrected chronic metabolic acidosis is an additional factor that may contribute to poor growth [27].



(Reproduced from Mehls O. Schaefer F: Endocrine, metabolic and growth disorders-patterns of growth and maturatin in chronic renal failure-impact of developmental stage. In holiday MA, Barratt TMJ vner ED. editors: *Pediatric nephrology*. Baltimore, 1994, Williams & Wilkins, pp 1260–63.)

Fig. 1 Typical growth pattern in patients with congenital chronic kidney disease is shown in *red*. Loss of statural height predominates in infancy and adolescence, with growth parallel to the normal curves in mid-childhood. The shaded area represents the normal range (3–97%). (Reproduced with permission from Mehls and Schaefer [19])

Disturbances in the growth hormone (GH)–insulin growth factor 1 (IGF-1) axis plays yet another important role in CKD-related growth retardation. The nature of the disturbance depends somewhat on age and involves impaired Janus kinase 2 (JAK2)-signal transducer and activator of transcription (STAT) signal transduction following GH binding to the receptor and increased expression of the growth plate suppressor of cytokine signaling (SOCS2), as described in greater depth later in this chapter [28–31].

Evaluation of Growth, Development, and Nutritional Status in CKD

Because of the high risk for impaired growth, and the unquantified (but at least theoretical) risk for protein energy wasting in children with CKD, it is recommended that their growth and nutritional status be evaluated regularly. The Pediatric Renal Nutrition Taskforce (PRNT) 2020 Clinical Practice Recommendations on the assessment of nutritional status in children with CKD provides guidance on the measures to follow and at what intervals [32]; these recommendations, informed by the 2008 Kidney Disease Outcomes Quality Initiative (KDOQI) recommendations [33], are summarized in Table 1. Recommendations differ for children under 1 year old and for those 1–3 years old versus older children, based on the different factors influencing growth among infants and very young children compared to older children with CKD.

Growth and nutritional status are assessed by measuring recumbent length (in children 24 months of age or younger) or standing height (children >24 months old) and weight. For children under 2–3 years of age, head circumference is also measured. Length should be measured in infants younger than 2 years using a length board, and height should be measured in older children using a wall-mounted stadiometer. Ideally, the same well-trained person should take the measurement at each assessment. Serial measures of length or height can be used to determine height velocity (cm/year). Weight should be measured when the child is determined to be at his/her euvolemic or "dry" weight, or the dry weight should be estimated based on clinical status. Dry weight (in kilograms) is divided by length or height (in meters) squared to calculate the body mass index (BMI). To determine the adequacy of growth and nutritional status, these measures (length or height, BMI, and height velocity) must be compared with reference values for healthy children by plotting them on growth curves and calculating standard deviation scores (SDS). SDS represent the difference, in standard deviation units, between an individual and the mean for healthy children of the same sex and age.

Growth Reference Values The World Health Organization (WHO) growth reference standards [34] provide the recommended reference for growth parameters from birth to 2 years; these standards represent ideal growth, which should be the goal for children with CKD. After 2 years, the WHO growth standards may be used up to age 5 years and the WHO growth reference data thereafter, or country-specific reference curves may be used where available. The reference population used to generate the WHO growth standards was of broad ethnic diversity; only 3% of the variability in length within the WHO population could be attributed to the country of origin [34], suggesting

Table 1 Parameters and frequency of nutritional assessment in children with CKD stages 3b–5D[a]

Measure	Age 0–1 year[b] Minimum interval (weeks)		Age 1–3 year Minimum interval (months)		Age > 3 years Minimum interval (months)	
	CKD 3b-5	CKD 5D	CKD 3b-5	CKD 5D	CKD 3b-5	CKD 5D
Height or length for age centile or SDS	6	2–4	2	1	3	3
Height velocity for age centile or SDS	N/A	N/A	3	2	6	6
Estimated euvolemic weight and weight for age centile or SDS	6	4	2	1	3	3
BMI for height-age centile or SDS	N/A	N/A	2[c]	1[c]	3	3
[c]Weight for length centile or SDS	6	6	2[c]	1[c]	N/A	N/A
Head circumference for age centile or SDS	6	4	2	2	N/A	N/A
Dietary intake	8	8	3	3	6	4

[a] Earlier stages of CKD and other kidney diseases are not addressed in this table, as clinical conditions can vary, and physician discretion is required. Further details are addressed in [33]

[b] Infants and toddlers cannot be categorized with the stage of CKD as there may be spontaneous improvement in kidney function up to 2 years of age. A suggested method to characterize the stage of CKD in this age group is to use the KDIGO 2012 clinical practice guideline for the evaluation and management of chronic kidney disease, substituting a GFR > 1 but ≤2 SDS below the mean for moderate reduced GFR (stages 3–4) and severely reduced GFR > 2 SDS below the mean for stage 5 [161]

[c] Weight for length should be used for children <2 years of age or up to 3 years if accurate standing height measurement is not possible

that the growth standards reflect a reasonable expectation for growth regardless of ethnicity. All WHO growth charts can be found at http://www.who.int/childgrowth/en/.

Special growth curves are available for a variety of special populations, including Trisomy 21, Turner syndrome, and premature infants [35, 36]. Diagnosis-specific curves were constructed from fairly small reference populations but provide useful guidance on expected growth in these unique groups. Premature infants should have growth assessed relative to their corrected age rather than chronological age. Corrected age is determined by subtracting the number of weeks early that the child was born from the chronological age. Separate curves are available for low-birth-weight (1,500–2,500 g) and very-low-birth-weight (<1,500 g) infants [37].

Assessing Linear Growth

When assessing the adequacy of growth, it is important to consider the child's height not only relative to the appropriate reference group, but also relative to his or her genetic potential. Although many factors influence growth in addition to genetic factors, a child's adult height potential may be estimated from the sex-adjusted midparental height. Midparental height is calculated from the heights of the biological parents. For girls, 13 cm is subtracted from the father's height and averaged with the mother's height. For boys, 13 cm is added to the mother's height and averaged with the father's height. This average of parental heights is then plotted at age 20 years on the growth chart relevant for the sex of the child; the heights 8.5 cm above and below the calculated midparental height represent two standard deviations around this estimate [33].

Determination of bone age may be helpful in providing an idea as to the remaining growth potential of the long bones. By convention, bone age is evaluated by obtaining a left hand and wrist radiograph. This is compared with the images of "standard" hand/wrist radiographs from children of different ages in the Greulich and Pyle skeletal age atlas [38]. However, this method is imprecise and subject to interobserver variability. Bone age should be recognized as an estimate of skeletal maturity, rather than a precise measure, and should be interpreted in the context of the sexual maturity and overall health.

Height- or Length-for-Age Percentile or SDS The height- or length-for-age SDS is calculated by subtracting the child's height from the mean height for children of the same age and sex and dividing by the standard deviation for children of the same age and sex. A SDS of zero represents an average height; a positive SDS indicates above average height, and a negative SDS indicates below average height. The percentile can either be estimated by plotting on the curve, on which percentile lines are marked, or by calculating it from the SDS.

Height- or Length Velocity-for-Age Percentile or SDS Growth velocity, measured in cm/year, may be calculated to determine if the growth rate is appropriate for age. The simplest way to visualize growth velocity is to plot length or height on the growth curves to determine if the child is crossing percentiles. However, growth velocity can be assessed more precisely using growth velocity reference values. Growth velocity standards are available from the WHO for infants up to 24 months [39], and growth velocity reference values are available for older children [40, 41]; these can be used to calculate growth velocity SDS. A negative height velocity SDS indicates that the child is growing at a lower-than-average rate, resulting in a crossing down of percentiles. A positive height velocity SDS may indicate catch-up growth. Among children over 2 years old, growth velocity and growth velocity SDS can only be accurately estimated over intervals of a minimum of 6 months. However, height may be measured more frequently and plotted on the growth curves to give a general impression of growth adequacy.

Assessing Body Weight

The first step in determining the appropriateness of a child's weight is to estimate the euvolemic weight. This is generally referred to as the "target dry weight," since volume overload is the more common abnormality in CKD; this is discussed further in ▶ Chap. 74, "Assessment of Volume Status in Chronic Kidney Disease." However, some children with CKD may also be at risk for volume depletion due to high urine volumes (e.g., renal dysplasia and cystinosis). Physical findings such as edema and jugular venous distention indicate volume overload. Hypertension is also commonly a sign of fluid overload in patients on maintenance dialysis [42]. In terms of laboratory assessment, hypoalbuminemia or anemia may be a marker for fluid overload. In contrast, thirst, tachycardia, decreased skin turgor, and sunken eyes and/or fontanelle signify volume depletion. In maintenance dialysis patients, response to dialytic fluid removal (hypotension and cramping) may give clues as to the volume status of the patient. Use of blood volume monitoring during a HD session can also be beneficial; this is discussed further in ▶ Chap. 76, "Chronic Hemodialysis in Children." Estimation of target dry weight is difficult, particularly in growing children, in whom weight is expected to increase over time. Most importantly, errors in the estimation of target dry weight may have an important impact on the assessment of the appropriateness of body weight relative to height. For example, an overestimation of target dry weight representing 10% of the body weight will result in a BMI SDS about 0.5–1.0 SD units above what it would be at the true target dry weight.

Estimated Dry Weight and Weight-for-Age and Body Mass Index-for-Age Percentiles or SDS Once the target dry weight has been estimated, it should be plotted on the weight-for-age curves and the SDS calculated. Weight-for-age cannot be interpreted in isolation because it will be low in children who are short for age. Therefore, weight-for-age should be interpreted in the context of the height-for-age percentile or SDS. Appropriateness of weight relative to height is best assessed using weight-for-length percentiles in younger children (<2 years) or BMI in older children.

BMI, calculated by dividing weight (kg) by height (m) squared, provides a means of evaluating the appropriateness of a child's weight relative to height. Because a normal BMI changes with age-related changes in body proportions and body composition, the raw BMI is not meaningful in children. Like other growth parameters, BMI must be expressed as a percentile or SDS relative to age and sex [17] to allow meaningful and consistent interpretation regardless of age. The WHO does provide pediatric BMI reference values from birth [34]; country-specific reference values are also available in some countries.

There are some caveats to the assessment of BMI in children with CKD due to the high prevalence of growth retardation and delayed sexual maturation. If BMI is expressed relative to chronological age in a child with growth and/or maturational delay, this will result in inappropriate underestimation of his/her BMI compared to peers of similar height and developmental age. This problem can be avoided by expressing BMI relative to height-age in children with CKD [43]. Height-age is the age at which the child's actual height would be on the 50th percentile. This approach is currently recommended for children with CKD whose height is below the third percentile for age and who have not yet attained their final adult height [32]. When growth and sexual maturation are complete, BMI should be expressed relative to chronological age.

It is important to recognize that the BMI SDS only provides information on whether the child's weight is above or below the normal healthy range for children of the same height, sex, and age; it does not distinguish fat from lean weight. Nevertheless, BMI SDS remains a useful index of nutritional status. As in healthy children, the BMI percentile or SDS can be used to classify children with CKD as underweight, normal weight, overweight, or obese. The WHO defines underweight or "thinness" as a BMI-for-age less than the third percentile (SDS less than − 2.0), overweight as BMI-for-age greater than the 85th percentile (or more than about 1 SD above the average), and obesity as BMI-for-age above the ~97th percentile (>2 SD above the average) [44]. However, it must be recognized that the risk associated with any of these categories in a CKD population remains controversial. These are distributional cutoffs; no evidence-based definitions link underweight or thinness to poor outcomes in the general population. Although obesity and overweight have been associated with adverse outcomes in otherwise healthy adults, the ability of these categories to predict poor outcomes in the pediatric CKD population is unknown. Large studies of adult hemodialysis patients showed an inverse relationship between BMI and mortality risk. These studies found no clear BMI threshold above which the mortality risk stabilized or began to increase, even as BMI increased above 30 [45, 46]. A smaller study, also of adult hemodialysis patients, found a U-shaped relationship between BMI and mortality risk, with higher mortality risk among those with BMI <17 or >23 compared to those with BMI between 17.0 and 18.9 [47]. A similar U-shaped association has been seen in children with stage 5 CKD: mortality risk was lowest among children with a BMI SDS around +0.5. A 1.0 SD unit difference in BMI SD score in either direction was associated with a 6% higher risk of mortality [10] which represents a fairly small effect. All of these studies can only conclude that there is an association between BMI and outcome; a causal relationship has not been established. Nonetheless, BMI, interpreted in the overall clinical context, can provide useful information to clinicians caring for children with CKD.

Head Circumference-for-Age Percentile or SD Score Like for healthy children ≤2–3 years of age, head circumference should be measured regularly and plotted on the head circumference-for-age curves in children with CKD. The WHO growth standards are the most appropriate reference curves [48]. In the past, infants with CKD were shown to be at risk for poor head growth – reflecting poor brain growth. However, more recent studies, in an era where nutritional support was likely more consistent, have demonstrated mostly normal head growth in infants with CKD [49]. Nevertheless, this measure is still recommended. Head circumference assessment should be coupled with intermittent developmental assessments in this population.

Other Measures

In addition to growth parameters, there are a few other methods that are useful in assessing nutritional status. These include appetite assessment, dietary intake, a nutrition-focused physical exam, and biochemical parameters.

Appetite Assessment A simple assessment of appetite may be a very useful measure of overall well-being. Patients and families can be asked to characterize appetite as very good, good, fair, poor, or very poor at clinical visits. A "very poor" appetite has been associated with a higher risk for hospitalization and poorer quality of life compared with all other categories in children with CKD [50].

Dietary Intake Information on dietary intake allows the treating team to evaluate the adequacy of a patient's intake before significant adverse changes in body composition or growth result. This is particularly important in infants, in whom poor intake is expected. A skilled registered dietician is able to assess dietary intake using a variety of methods. Dietary records allow the dietician to estimate the daily intake of calories, macronutrients (carbohydrates, protein, and fat), vitamins, and minerals. Prospective three-day dietary diaries provide unbiased estimates of energy intake in children under 10 years old. However, underreporting is common among adolescents [51, 52] making 24-h recalls a potentially more suitable option in adolescents. Given the inability of the 24-h recall method to capture the day-to-day variability in intake, it is recommended that three 24-h recalls (including one weekend day and two weekdays) be conducted for a more complete evaluation of intake [32].

Nutrition-Focused Physical Examination The first step in a nutrition-focused physical examination involves a general assessment of volume status, including the presence of edema. This is necessary to allow estimation of dry weight. The physical exam also includes inspection and palpation of areas where there may be muscle and/or fat wasting. Skin, hair, and nails should be examined for signs of micronutrient deficiencies. The nutrition-focused physical exam can be used as part of the subjective global nutritional assessment [53], which includes anthropometric measures, appetite changes, gastrointestinal symptoms, and dietary intake. The subjective global nutritional assessment generates a risk score for malnutrition. Although the subjective global nutritional assessment has limited evidence in the pediatric CKD population [54], it has been validated in a general pediatric population and in adults with CKD [55].

Biochemical Parameters There are few validated biochemical parameters that are useful in assessing nutritional status. The normalized protein catabolic rate (nPCR) is currently the only measure validated for use in pediatric CKD; evidence exists for its validity in adolescents treated with maintenance hemodialysis [56]. The nPCR provides an objective estimate of dietary protein intake; an nPCR of ≥ 1 indicates adequate protein intake in adolescents 13–19 years old on hemodialysis [32]. Sequential measures of nPCR in younger children may be useful in following trends when interpreted in the context of dietary intake, weight gain, and growth.

Serum albumin is frequently suggested as a measure of nutritional status. However, its interpretation is substantially confounded by other factors. Fluid overload will decrease albumin, as will systemic inflammation. Unless all other causes of hypoalbuminemia have been excluded, albumin is not recommended as a method of assessing nutritional status. Urea is also often suggested as a parameter correlated with nutritional status. However, there is very limited evidence of its value as such.

Protein Energy Wasting (PEW)

Adverse changes in nutrition and body composition are prevalent in patients with CKD and are associated with significant morbidity and mortality. Among the many risk factors that affect outcomes in these patients, especially those with advanced CKD, is a state of protein energy wasting (PEW), characterized by anorexia, poor weight gain, and low muscle mass. This is associated with major adverse outcomes, such as an increased frequency of hospitalization [57]. The terms wasting, cachexia, and malnutrition have historically been used interchangeably. However, to be more specific, malnutrition results from the improper intake or absorption of nutrients despite a preserved appetite and manifests as weight loss associated with adaptive metabolic responses. In contrast, wasting syndromes are characterized by maladaptive responses, including anorexia and a high metabolic rate. As a result, wasting syndromes are associated with low serum albumin, weight loss, diminished muscle mass, and normal or increased fat mass. Although inadequate nutritional intake can be partly responsible for the nutritional derangement, recent studies have shown that many other factors, including systemic inflammation, endocrine disturbances, and abnormal neuropeptide signaling, may significantly contribute to a wasting syndrome in the setting of CKD [57]. The concept of protein energy wasting was defined by the International Society of Renal Nutrition and Metabolism (ISRNM) as a state of nutritional and metabolic derangements in patients with CKD characterized by the simultaneous loss of systematic body protein and energy stores, leading to the loss of muscle and fat mass and ultimately cachexia [58]. Thus, PEW is a pathological state in which there is a persistent decline or wasting of both protein deposits and energy reserves. A recent study made an important contribution to the definition of PEW in children with CKD by including growth/growth velocity as a diagnostic parameter [59]. The addition of this indicator to existing adult criteria improved the prediction of hospitalizations, and it is thus important that growth be considered when assessing children at risk for PEW. Abraham et al. provided the criteria for pediatric PEW (Table 2) in the analysis from the CKiD study. Among the 528 children analyzed in this study [median age 12 years; median glomerular filtration rate (GFR) 45 ml/min/1.73 m^2], PEW prevalence ranged from 7–20% depending on the definition used. There was also a higher, but not statistically significant, prevalence of PEW [odds ratio (OR) = 1.5] in CKD stages 4 and 5. Interestingly, low muscle mass was reported to be highly prevalent and trended toward a higher frequency

Table 2 Diagnostic criteria for PEW in children with CKD [59]

Biochemical – Serum total cholesterol (TC) $<$ 100 mg/100 ml; serum albumin $<$3.8 g/100 ml, serum transferrin $<$140 mg/dl; CRP $>$3 mg/L
BMI for height/age and sex $<$5th percentile at diagnosis of CKD or a decrease in BMI $\geq$ 10% between the first and second annual visits
Mid-upper-arm circumference (MUAC) for height/age and sex $<$5th percentile or a decrease in MUAC $\geq$10% between annual visits
Decreased appetite
Poor growth – defined as either short stature [a height/age and sex percentile $<$3% or poor growth velocity (decrease in height for age and sex percentile of $\geq$10% between annual visits)

with lower GFR [59]. Foster et al. also evaluated whole/regional lean and fat mass in 143 children with CKD and 958 healthy individuals. They reported that leg lean mass Z-scores were similar in CKD stages 2–3, but were lower in stages 4–5 compared with controls [60].

Decreased physical activity is likely to play a major role in the pathophysiology of PEW. There has been increasing recognition of the benefits of regular physical activity for CKD patients, which improves cardiac function, decreases cardiovascular risk factors, enhances muscular strength, reduces the number of atrophic muscle fibers, and increases exercise capacity. A recent systematic review confirmed that progressive resistance training induces skeletal muscle hypertrophy, increases muscular strength, and improves health-related quality of life of CKD patients [61]. Indeed, exercise is also important in the management of children with ESKD, especially those with poor nutrition and growth failure [62]. Although its long-term effect on clinically relevant outcomes remains to be determined, resistance exercise training is safe, effective, and costless, and should be encouraged as a potential countermeasure for PEW [61].

As noted previously, perturbations in appetite-regulating hormones such as leptin and ghrelin may contribute to anorexia in CKD [63]. As the kidney degrades leptin, CKD is independently associated with a peripheral increase in circulating leptin concentrations that are strongly and inversely correlated with GFR in children [63]. Experimental anorexia and cachexia of CKD can be ameliorated by blockade of leptin signaling through the hypothalamic melanocortin-4 receptor [64]. Human data on leptin and CKD–PEW are inconclusive. With body fat mass loss, serum leptin will primarily reflect these fat stores, thus obscuring any links to appetite [63]. Cheung et al. tested whether treatment with a pegylated leptin receptor antagonist (PLA) attenuates cachexia in mice with CKD. PLA stimulated appetite and weight gain, improved lean mass and muscle function, reduced energy expenditure, and normalized the expression of proinflammatory muscle cytokines such as IL-1α, −1β, and − 6 and TNF-α. These results suggest that leptin antagonism may represent a viable therapeutic strategy for cachexia in CKD [65]. Increased total ghrelin levels in CKD are primarily due to the decreased degradation of ghrelin in the kidney. Recent studies have suggested that elevated des-acyl ghrelin levels could be involved in the anorexia of CKD patients [66]. Short-term ghrelin administration can improve appetite, but long-term trials of ghrelin in CKD patients have not been reported [67].

Increased energy expenditure despite caloric insufficiency is an important feature of cachexia often observed in CKD. Ikizler et al. carefully studied adult ESKD patients on maintenance hemodialysis and showed a higher resting energy expenditure (REE) which was further increased during hemodialysis [68]. Wang et al. studied a sizable population of 251 adult peritoneal dialysis patients, who were classified by REE tertiles. They showed that patients in the upper and middle tertiles of REE showed a significantly higher risk of all-cause mortality compared to those patients in the lower REE tertile [69].

Adipose tissue and muscle are both involved in energy metabolism. Uncoupling protein (UCP)-1 is important for thermogenesis, while UCP-2 and UCP-3 regulate mitochondrial energy metabolism. Increased UCP expression stimulates

thermogenesis while inhibiting ATP synthesis. Cheung et al. showed that adipose tissue's UCP content was increased while ATP content was significantly decreased in CKD. This phenomenon is described as adipose tissue browning and provides an important mechanism for hypermetabolism in CKD [70].

Various observational studies and prospective randomized trials have provided convincing evidence that recombinant human growth hormone (rhGH) can improve nutritional biomarkers and LBM in maintenance dialysis patients. A large multicenter randomized controlled trial was designed to investigate whether rhGH reduces mortality and morbidity and improves overall health in adult patients on dialysis with low serum albumin. Although the study was terminated early because of low recruitment, rhGH therapy improved some cardiovascular risk factors, but did not reduce mortality or ameliorate nutritional indexes [71]. Recent findings in rodent studies have also suggested that increased serum levels of PTH [72] and/or vitamin D deficiency [72] may be significant factors for CKD cachexia. Cheung et al. demonstrated improvement in muscle wasting and cachexia by vitamin D repletion, an intervention that was accompanied by normalization of serum 25-hydroxyvitamin D3 and 1,25-dihydroxyvitamin D3 concentrations and attenuation but not normalization of the serum PTH concentrations in CKD mice. Based on these results, it was postulated that the impact of secondary hyperparathyroidism may be less significant than the influence of vitamin D insufficiency in CKD-associated cachexia and muscle wasting [73]. However, these preliminary preclinical studies ideally need to be confirmed by randomized trials in children with CKD. The clinical manifestations and factors contributing to PEW in children with CKD are summarized in Fig. 2 [74].

Nutritional Requirements

The nutritional requirements for children with CKD and those undergoing maintenance dialysis are generally based on the published recommended dietary allowances (RDA) for healthy children, and the basis for the RDA values varies for different nutrients. Currently, the RDAs for a number of nutrients have been replaced by dietary reference intakes (DRIs) that are comprised of a set of four reference values: *estimated average requirement* (EAR), *recommended dietary allowance* (also popularly know as recommended daily allowance) (RDA), *adequate intake* (AI), *and tolerable upper intake level* (UL) [75]. Because multiple national and international bodies have published slightly different recommended values and have used terms that are not directly comparable, the Pediatric Renal Nutrition Taskforce (PRNT) decided to take a more pragmatic approach and has recently introduced the novel term suggested dietary intake (SDI), which comprises a range of values [76].

Energy Requirements

Energy requirements are determined by lean body mass, are modified by growth, current nutritional status, and physical activity, and are influenced by genetics, ethnicity, and environment. The optimal energy intake from food should maintain normal body mass, promote growth and development, and support the level of physical activity performed by the subject. Studies that have investigated the optimal requirements for energy in children with CKD found no difference in the resting energy expenditure (REE) (also known as basal metabolic rate (BMR)) between these children and healthy children, after adjusting for lean body mass [77]. Most studies in children with CKD have reported that a dietary energy intake of around 100% of the estimated energy requirement (EER) for chronological age resulted in acceptable growth. The energy intake can be further adjusted based upon response in terms of the rate of weight gain/loss that is individually adjusted for the physical activity level (PAL) and BMI [75, 78].

Energy requirements for patients treated with maintenance HD or PD are similar to those of pre-dialysis patients. In children receiving maintenance PD, variable glucose absorption takes place from dialysis fluid depending on the PD modality, dialysate glucose concentration, and peritoneal membrane solute transport capacity [79]. In a study of 31 children older than 3 years on ambulatory PD therapy, the mean energy intake derived from peritoneal glucose absorption was 9 kcal/kg/day [80]. Since many children who receive chronic PD are underweight, the prescribed energy intake in them should exclude the estimated calorie absorption from the dialysate, while in the setting of obesity, the caloric contribution from dialysate should be taken into account when estimating energy requirements.

Historically, a number of studies have shown that pediatric patients with CKD exhibit inadequate dietary energy intake in association with worsening kidney function [8]. In a prospective study of growth failure in children with CKD, caloric intakes <80% of the RDA for age were present in more than one-half of food records obtained [81]. While an inadequate voluntary energy intake has been clearly demonstrated in infants with CKD [82], energy intakes for older children are generally normal relative to their body size [81]. In contrast to prior publications, the recent assessment of dietary intake in children with CKD from the CKiD study revealed that the median energy consumption levels were higher than recommended values in all age groups. While there was a decreased energy consumption with the fall in GFR ($p = 0.003$), younger children were more likely to exceed the recommended caloric intake than their older counterparts ($p < 0.001$) [83].

Maximizing caloric intake has been noted to be particularly effective in improving height velocity in infants with CKD or receiving dialysis [82, 84]. As children older than 2 years of age with CKD do not generally experience catch-up growth, the provision of adequate energy intake early in life is crucial.

While worldwide, undernutrition in children with CKD remains a concern, recent data from the International Pediatric Peritoneal Dialysis Network (IPPN) reported a 19.7% prevalence of overweight/obesity (compared with 8.9% underweight) in children at the start of maintenance PD [85]. Multivariate analysis revealed that nasogastric/gastric tube feeding was an independent predictor of overweight/obesity [86]. Accordingly, prevention and treatment of obesity in patients with CKD is important. Energy requirements for overweight or obese children are lower than normal and can be estimated by using equations specific for children heavier than a healthy weight [75].

Protein Requirements

The usual dietary protein intake (DPI) requirement is based on nitrogen losses in the urine, stool, hair, and nails, in addition to the extra protein required for growth. It is important that the required protein intake be accompanied by adequate sources of nonprotein energy (i.e., carbohydrates and fats) as inadequate caloric intake results in inefficient use of dietary protein as a calorie source, with a resultant increased generation of urea. Thus, ensuring that caloric needs are met is an important step in assessing protein requirements. It is advised that at least 50% of the total protein intake consists of protein of high biologic value such as that derived from milk, eggs, meat, fish, and poultry. However, more recently, it has been argued that plant-based proteins are not only nutritionally adequate, but have other beneficial effects that may favor their use in CKD patients [87].

The 2009 KDOQI pediatric nutrition guidelines recommended maintaining the DPI at 100–140% of the DRI for ideal body weight in children with CKD stage 3 and 100–120% of the DRI in children with CKD stages 4–5 (Table 3) [33]. The recently published PRNT clinical practice recommendations suggest that the target protein intake in children with CKD 2–5D should be at the upper end of the recommended intake to promote optimal growth, and the DPI should not be reduced below the lowest end of the recommended range which is considered the minimum safe amount [76].

As there is a nearly linear relationship between protein and phosphate intake, the consumption of a high-protein diet in patients with CKD is frequently associated with the development of hyperphosphatemia [88]; this is discussed further in ▶ Chap. 72, "Chronic Kidney Disease – Mineral and Bone Disorder (CKD-MBD)." Conversely, low-protein diets decrease the development of hyperphosphatemia, metabolic acidosis, hyperkalemia, and other electrolyte disorders. Two randomized controlled trials comparing low-protein versus normal protein diets in children with CKD [89, 90] showed that a modest reduction in protein intake, with maintenance of energy intake greater than 80% RDA in both groups, did not adversely affect growth, serum albumin, or the rate of CKD progression over 2–3 years. Hence, although there is no evidence for a nephroprotective effect of dietary protein restriction, these studies did provide evidence that dietary protein intake can be safely restricted to 0.8–1.1 g/kg/d in children older than 2 years with CKD [90].

While the spontaneous DPI is reduced in association with CKD progression in a manner similar to that of energy intake, the DPI typically still remains far in excess of the average requirements, ranging from 150–200% of the RDA [81, 90]. The recent assessment of dietary intake from the CKiD study revealed that the median protein intake exceeded the recommended levels in all age groups [83].

There are situations in which the dietary protein requirements may be increased relative to the general recommendations. In patients with ongoing proteinuria or during recovery from intercurrent illness, the recommended intake may be adjusted to height-age instead of chronological age if evidence of protein deficiency exists or persists. Modification of protein recommendations may also be necessary in obese children. Obese individuals have a greater percentage of

Table 3 Recommended dietary protein intake in children with CKD stages 3–5 and 5D [33]

Age	DRI (g/kg/d)	Recommended for CKD stage 3(g/kg/d) (100–140% DRI)	Recommended for CKD stages 4–5 (g/kg/d) (100–120% DRI)	Recommended for HD (g/kg/d)[a]	Recommended for PD (g/kg/d)[b]
0–6 months	1.5	1.5–2.1	1.5–1.8	1.6	1.8
7–12 months	1.2	1.2–1.7	1.2–1.5	1.3	1.5
1–3 years	1.05	1.05–1.5	1.05–1.25	1.15	1.3
4–13 years	0.95	0.95–1.35	0.95–1.15	1.05	1.1
14–18 years	0.85	0.85–1.2	0.85–1.05	0.95	1.0

[a] DRI + 0.1 g/kg/d to compensate for dialysis losses

[b] DRI + 0.15–0.3 g/kg/d depending on patient age to compensate for peritoneal losses

body fat, which is much less metabolically active than lean body mass. Therefore, it is believed that basing protein (and energy) requirements of obese individuals on actual weight may overestimate requirements. Conversely, the use of ideal body weight as a reference for an obese person does not take into account the increase in body protein needed for structural support of extra fat tissue. Therefore, a common practice is to estimate protein requirements of obese individuals based on an "adjusted" weight (i.e., adjusted weight = ideal weight for height + 25% × [actual weight − ideal weight], where 25% represents the percentage of body fat tissue that is metabolically active) rather than their actual body weight [91].

Additionally, the optimal protein intake for pediatric patients on maintenance dialysis has not yet been well defined. Although dialyzed children require larger amounts of protein per unit of body weight compared to adults in order to grow in size and lean body mass, this demand is fully accounted for by the age-adjusted pediatric DRI. Hence, the only additional dietary protein requirement is the replacement of dialytic nitrogen losses. In those on long-term PD therapy, daily peritoneal protein losses decrease with age across childhood from an average of 0.28 g/kg in the first year of life to less than 0.1 g/kg in adolescents [92]. Peritoneal amino acid losses add approximately one-third to the nitrogen lost with protein, resulting in a total additional dietary protein requirement of 0.15–0.35 g/kg, depending on patient age (Table 3).

Patients with high peritoneal membrane transport characteristics tend to have low serum albumin levels, likely due to increased peritoneal protein losses; these patients may have slightly greater protein requirements.

Amino acid and protein losses during HD vary according to dialyzer membrane characteristics and reuse. Whereas losses have not been quantified in children, an average of 8–10 g of amino acids and less than 1–3 g of protein are lost per HD session in adults [93]. On the basis of three HD sessions per week for a 70 kg adult, this equates to 0.08 g/kg/day. Assuming that dialytic amino acid losses are linearly related to urea kinetics, children can be expected to have similar or slightly higher amino acid losses than adults and an added DPI of 0.1 g/kg/d should compensate for pediatric HD losses.

Finally, there is some concern that a high DPI may prove harmful when consumed by dialyzed children. In a DXA study of body composition in 20 children on long-term PD therapy with a mean DPI of 144% RDA, protein intake inversely correlated with bone mineral density, bone mineral content, fat-free mass, and plasma bicarbonate level, suggesting that a high protein intake may cause tissue catabolism and bone loss by worsening metabolic acidosis [94]. However, the most convincing argument for limiting DPI in dialyzed children is derived from the solid evidence supporting the key etiologic role that dietary phosphorus load has in the pathogenesis of dialysis-associated calcifying arteriopathy. As noted previously, there is a nearly linear relationship between protein and phosphorus intake, which results in the frequent association between high dietary protein and hyperphosphatemia [95]. Hence, it appears appropriate to limit dietary protein intake in children on dialysis to the safe levels known to ensure adequate growth and nutrition in healthy children.

Lipid Requirements

Dyslipidemia is a frequently recognized complication of CKD in children [96], occurs relatively early in the course of CKD (i.e., stage 3 CKD), and increases in prevalence with decreasing kidney function [96]. The CKiD study reported the presence of dyslipidemia in 44% of 250 children with mild to moderate CKD, with the most common abnormality being hypertriglyceridemia in 75% [97]. Declining GFR and worsening proteinuria are independently associated with worsening dyslipidemia [96]. The dyslipidemia pattern seen in children with CKD has been labeled "atherogenic" and in addition to hypertriglyceridemia, there are high levels of VLDL and intermediate-density lipoproteins (IDLs), low levels of HDL particles, and normal or modestly increased levels of total and low-density lipoprotein (LDL) cholesterol [98].

The 2013 KDIGO CPG for lipid management in CKD recommends obtaining a lipid profile (total, LDL, and HDL cholesterol, and triglycerides) in all children with newly diagnosed CKD (including those receiving dialysis or with a kidney transplant), and with annual follow-up measurements [99], while the optimal management of dyslipidemia in children with CKD is not clearly defined. Treatment of malnutrition related to impaired kidney function is essential and should supersede any potential rise in lipid levels that might result from it. On the contrary, prevention and treatment of obesity in patients with CKD is an important strategy to reduce the risk of hyperlipidemia. Correction of metabolic acidosis, vitamin D therapy, and correction of anemia with erythropoietin each also seem to have some normalizing effect on dyslipidemia in children with CKD [100–102]. The KDOQI dyslipidemia guidelines' recommendations [103], endorsed by the KDOQI cardiovascular guidelines [104], state that dietary and lifestyle recommendations made for adults are also appropriate for post-pubertal children and adolescents with CKD. Therapy with statins or statin/ezetimibe combination is not recommended for children with CKD less than 18 years of age [99].

The expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents recommends that in children with hypercholesterolemia, less than 25–30% of calories should come from dietary fat, of which $\leq$7% should be from saturated fatty acids; the daily cholesterol intake should be $<$200 mg [105]. For serum triglyceride $>$150 mg/dL, therapeutic lifestyle changes (TLC) are recommended along with a low-fat diet and a low intake of simple carbohydrates [99]. The child should be encouraged to ingest complex carbohydrates in lieu of simple sugars and concentrated sweets and to use unsaturated fats such as oils and margarines from corn, safflower, and soy.

High intakes of n-3 polyunsaturated fatty acids (omega-3 fatty acids [n-3 FA], docosahexanoic acid [DHA], and eicosapentanoic acid [106]) have been associated with decreasing triglyceride levels and a decreased risk of heart disease [107]. Therefore, EPA and DHA, found almost exclusively in fish and marine sources, should be provided in the diet; the best sources are fatty fish (e.g., tuna, mackerel, trout, salmon, herring, sardines, and anchovies). Although n-3 FAs have been found to be extremely safe by both Health Canada and the US Food and Drug Administration, there is insufficient evidence to recommend routine use of n-3 FAs to treat hypertriglyceridemia in children with CKD.

Dietary fiber, particularly naturally occurring viscous fiber, reduces total and LDL cholesterol levels and high intakes have been associated with reduced rates of CVD. The AI for total fiber is based on daily caloric intake and is 14 g/1000 kcal/d for all children 1 year and older. Dietary fiber is found in most fruits, vegetables, legumes, and whole grains, which are foods restricted in low-potassium and low-phosphorus diets; therefore, meeting normal daily fiber recommendations is challenging for children with CKD. Tasteless mineral- and electrolyte-free powdered forms of fiber (e.g., Unifiber® and Benefiber®) are available to add to meals or drinks if children are unable to meet their recommended fiber intake by diet. High-fiber diets require additional fluid intake, which may not be possible for oliguric or anuric patients with a strict fluid restriction.

Bone Mineral Metabolism

Optimal control of bone and mineral homeostasis is essential, not only for the prevention of debilitating skeletal complications and the achievement of adequate growth, but also for the prevention of vascular calcification and cardiovascular disease. Complications of mineral bone disease (MBD) are, however, common and contribute to the high morbidity and mortality seen in children with CKD. The provision of adequate but not excessive amounts of calcium and phosphorus is thus an important part of CKD-MBD management; this

Table 4 Recommended SDI (suggested dietary intake) for calcium and phosphate in children with CKD stages 2–5D [108]

Age	SDI calcium (mg/day)	SDI phosphorus (mg/day)
0–< 4 months	220	120
4–< 12 months	330–540	275–420
1–3 years	450–700	250–500
4–10 years	700–1000	440–800
11–17 years	900–1300	640–1250

is discussed further in ▶ Chap. 72, "Chronic Kidney Disease – Mineral and Bone Disorder (CKD-MBD)." The SDI of calcium and phosphorus is provided in Table 4.

Calcium Adequate dietary calcium intake during childhood is necessary for skeletal development and acquisition of optimal peak bone mass. The current recommendation is that patients with CKD should achieve a calcium intake of 100% of the DRI, just as their healthy peers. The main dietary sources of calcium for children are milk, milk products, breast milk, and manufactured infant formulas. Infants and young children usually meet the DRI for calcium with the consumption of adequate volumes of breast milk/infant formula. All standard and most specialized infant milk formulas have a higher concentration of calcium compared to human milk, but lower than cow's milk or the formulas intended for older children. Formulas designed for infants must comply with set compositional criteria, providing a minimum amount of 50–60 mg of calcium per 100 calories and a Ca:P ratio between 1.1 and 2.0. The calcium content of reduced-fat dairy products is comparable to whole milk-derived products. The "milk and milk products" food group (milk, cheese, yogurt, cream, and ice cream) contribute 44–70% of dietary calcium intake, being highest in the younger age groups. "Cereal and cereal products" (grains made into pasta, rice, breads, breakfast cereals, and biscuits) contribute 16–28% of average daily calcium intake. The variations in foods eaten in different countries or cultures may alter the relative calcium intake from specific food groups [108].

Most problematic is the fact that the largest source of dietary calcium for most persons are dairy products which are also rich in phosphorus; in turn, phosphorus restriction in the patient with CKD universally leads to a decreased calcium intake. In these situations, calcium supplementation may be required as low phosphorus, high calcium containing foods such as collards, dandelion greens, kale, rhubarb, and spinach usually do not make up a substantial part of a child's diet. Several products fortified with calcium such as fruit juices and breakfast foods are commercially available, and limited studies have suggested that the bioavailability of calcium from these products is at least comparable to that of milk. Calcium can also be supplemented in medicinal forms such as carbonate (40% elemental calcium), acetate (25% elemental calcium), and gluconate (9% elemental calcium) salts of calcium that are used as phosphate binders. When used for calcium supplementation alone, ingesting these products between meals maximizes calcium absorption. Chloride and citrate salts of calcium should be avoided as the former may lead to acidosis in patients with CKD and the latter may enhance aluminum absorption.

Excessive calcium intake in conjunction with activated vitamin D analogs can lead to (i) hypercalcemia, (ii) adynamic bone disease, and (iii) systemic calcification. Therefore, the total calcium intake from diet and medications (including phosphate binders) should be within the DRI, and no more than twice the DRI, unless there are exceptional circumstances such as in infants with mineral-depleted bones. Accordingly, the KDOQI guidelines as well as the PRNT recommendations state that the combined elemental calcium intake from nutritional sources and phosphate binders should not exceed two times the DRI for age, except for ages 9–18 years (both genders) where two times the DRI (2600 mg) exceeds the tolerable upper intake level (UL) of 2500 mg [33, 108]. The serum level of total corrected calcium should be maintained within the normal range (8.8–9.5 mg/dL), preferably toward the lower end and definitely not more than 10.2 mg/dL. The calcium balance in patients undergoing maintenance dialysis is also affected by the dialysate calcium concentration; this is discussed further in ▶ Chap. 72, “Chronic Kidney Disease – Mineral and Bone Disorder (CKD-MBD).”

Phosphorus In an effort to prevent/control CKD-MBD and CVD, serum phosphorus concentrations above the normal reference range for age should be avoided in patients with advanced CKD. However, even during the earlier stages of CKD when the serum phosphorus levels are typically within the normal range, the dietary phosphorus load is an important determinant of the severity of hyperparathyroidism. Dietary phosphorus restriction decreases PTH levels and increases 1,25(OH)$_2$D, whereas a dietary phosphorus intake approximately twice the DRI for age aggravates hyperparathyroidism despite little or no change in the serum phosphorus level (the result of elevated FGF-23 levels and enhanced phosphorus excretion). It is important to note that higher physiological serum concentrations of calcium and phosphorus that are observed in healthy infants and young children presumably reflect the increased requirements for these minerals by the rapidly growing skeleton. Rickets due to phosphorus deficiency can occur in preterm infants whose diet provides insufficient quantities of phosphorus, as well as in infants and children with hypophosphatemia due to inherited disorders of renal phosphate transport. Hence, when dietary phosphorus is restricted to control hyperphosphatemia and SHPT, subnormal serum phosphorus values are equally important to avoid; this is discussed further in ▶ Chap. 72, “Chronic Kidney Disease – Mineral and Bone Disorder (CKD-MBD).”

Data from the USA for all age groups indicate that the highest contributors to phosphorus intake are milk, meat, and grains [109]. The highest percentage of dietary phosphorus comes from “milk and milk products” particularly in the younger age groups. Breast milk is relatively low in phosphate, having a concentration about one-half of most standard whey-based formulas and one-third of casein-based infant formulas. Phosphate additives, such as phosphoric acid and sodium phosphate, are used by the food industry to improve the texture, taste, appearance, and shelf-life of many processed foods and their presence, but not quantity, is usually indicated on the ingredient list [110]. In addition, inorganic phosphates, which are readily absorbed, are added to several medications, such as antacids and many antihypertensive medications, as an excipient that aids in dispersion of the active drug ingredient once ingested [111]. The phosphorus load from medications can make a meaningful contribution to the daily phosphorus intake, and thus should be reviewed carefully by the health care team.

The absorption of phosphorus from food depends on whether it is in an organic or inorganic form. Meats, fish, dairy, vegetables, grains, and nuts contain organic carbon-bound phosphorus, with a bioavailability between 30% and 70%. Plant-based organic phosphorus (including seeds and legumes) is stored in the form of phytate or phytic acid, which cannot be broken down by humans, reducing the bioavailability to 30–40%.

Current recommendations from KDOQI suggest that in children with CKD whose serum PTH concentration exceeds the target range but whose serum phosphorus concentration remains normal, the dietary phosphorus intake should be restricted to 100% of the DRI; in contrast, the intake should be restricted to 80% of the DRI (which usually corresponds to the lower limit of the SDI) when the serum phosphorus concentration exceeds the normal reference range for age [33, 78, 108].

Despite the need to restrict dietary phosphorus, most clinicians recognize that an overly restrictive dietary phosphorus intake can be ill advised as it may lead to an inadvertent poor dietary protein intake [112]. In addition, extremely low phosphorus diets are typically unpalatable. Young infants are characteristically managed with a low phosphorus containing milk formula such as Similac PM 60/40® (Abbott Nutrition), Renastart®, (Vitaflo Nutrition), Renalcal® (Nestle Health Sciences), or by pretreatment of breast milk, infant formula, and cow’s milk with sevelamer carbonate (Renvela®; Sanofi US) which can effectively reduce the phosphorus content in the supernatant by 80–90% [113]. Whereas some infants may require phosphorus supplementation in the form of sodium phosphate (Neutra-Phos) because of their higher physiological needs, most other patients with CKD require oral intestinal phosphate binders to control hyperphosphatemia. Although food labels rarely state the phosphorus content [110], chocolates, nuts, dried beans, and cola soft drinks are rich in phosphorus and should be avoided; nondairy creamers and certain frozen nondairy desserts may be used in place of milk and ice cream.

Vitamin D Vitamin D plays an important role in the management of CKD-MBD and its deficiency is a risk factor for SHPT and decreased serum 1,25 $(OH)_2D$ levels. The CKiD study observed vitamin D deficiency (<20 ng/mL) in 28% of 506 children at enrollment. Those with 25-hydroxyvitamin D [25(OH)D] deficiency were more likely to be of non-White race, older with higher BMI z-scores, lower milk intake, not receiving a vitamin D supplement, had more proteinuria, and had higher FGF-23 levels [114]. While the total 25(OH)D and vitamin D–binding protein (VDBP) levels are lower in healthy Black adults and Black children when compared to White individuals, the bioavailable 25(OH)D levels are not different [115]. Current guidelines suggest checking serum 25(OH)D levels once every 6–12 months in children with CKD stages 2–5 [33, 116]. If the serum level of 25(OH)D is <30 ng/ml, supplementation with vitamin D_2 (ergocalciferol) or vitamin D_3 (cholecalciferol) is suggested, with the specific dosing regimen dependent on the patient's age and the severity of the deficiency; it is important to note that intermittent megadose regimens are not recommended (Table 5). Further details on vitamin D deficiency in CKD and supplementation are discussed in ▶ Chap. 72, "Chronic Kidney Disease – Mineral and Bone Disorder (CKD-MBD)."

During supplementation, vitamin D intake from milk formula and fortified foods should also be taken into account. Serum calcium, phosphorus, and urinary calcium should be monitored during the high dose "intensive replacement phase" to evaluate for the development of vitamin D toxicity. Once patients are replete with vitamin D, supplemental vitamin D should be continued and 25(OH)D levels checked every 6–12 months [33, 116].

Acid-Base and Electrolytes

Acid-Base Status Infants and children normally have a relatively larger endogenous hydrogen ion load (2–3 mEq/kg) than do adults (1 mEq/kg); in turn, metabolic acidosis is a common manifestation of CKD in children and an important negative influence on growth. Furthermore, studies performed in adults and children have shown that

Table 5 Suggested treatment for Vitamin D supplementation in children with CKD and on dialysis [116]

Age	Serum 25 (OH)D level (ng/mL)[a]	Vitamin D status	Vitamin D supplementation Dose (IU/day)	Monitoring
Intensive replacement phase				
<1 year	–		600[b]	Serum and urinary calcium levels 1–3 monthly based on CKD stage 25(OH)D levels: after 3 months
>1 year[c]	<5	Severe deficiency	8000	
	5–20	Deficiency	4000	
	21–30	Insufficiency	2000	
Maintenance phase				
<1 year	>30[d]		400	25(OH)D levels: 6–12 monthly
>1 year[c]	>30[d]		1000–1200	

[a] To convert ng/mL to nmol/L multiply by 2.5

[b] In infants <1 year, a fixed dose is recommended irrespective of the level of 25(OH)D

[c] Consider adjusting dose by body size (weight or body surface area)

[d] If levels remain <30 ng/mL, then give doses per the "Intensive replacement" schedule for a further course of intensive replacement and recheck levels

chronic acidosis is associated with increased oxidation of branched-chain amino acids, increased protein degradation, decreased albumin synthesis, and a higher risk of CKD progression [117, 118]. Persistent acidosis also has detrimental effects on bone because it alters the normal accretion of hydroxyapatite into bone matrix and causes bone demineralization as bone buffers are increasingly used for neutralizing the excess acid load. Thus, it is recommended that the serum bicarbonate level should be maintained at or above 22 mEq/L in children with CKD by supplementing with oral bicarbonate as needed [33].

Sodium Sodium requirements in children with CKD are dependent on the underlying kidney disease and the degree of impaired kidney function. Children who have CKD as a result of obstructive uropathy or renal dysplasia are most often polyuric and may experience substantial urinary sodium losses despite advanced degrees of CKD. Sodium depletion adversely affects growth and nitrogen retention [119], and its intake supports normal expansion of the extracellular fluid volume needed for muscle development and mineralization of bone. It is important to note that normal serum sodium levels do not rule out sodium depletion and the need for supplementation. Sodium supplementation can be given as chloride or bicarbonate, depending upon the patient's acid-base status.

In contrast, children with CKD resulting from a primary glomerular disease, or those who are oliguric or anuric, typically require a sodium and fluid restriction to minimize fluid gain, edema formation, and hypertension. The sodium intake for children older than 2 years should be restricted to <1,500 mg (65 mmol) [106], which corresponds to sodium intake of 1–2 mmol/kg/day for those younger than 2 years. These patients should be advised to avoid processed foods and snacks from fast-food restaurants as a substantial amount of sodium can come from salt added during food processing. A cross-sectional study of dietary intake in the CKiD cohort revealed that fast foods were the largest single source of sodium, contributing 9.4% of the total intake; the dietary sodium intake increased with age and exceeded the recommended maximum intake in all age groups [83]; the median sodium intake was 83 mg (3.6 mmol) per kg per day [120].

Infants receiving PD are particularly predisposed to substantial sodium losses, even when anuric. High ultrafiltration requirements per kilogram of body weight result in removal of significant amounts of sodium chloride. These losses are not adequately replaced through the low sodium content of breast milk (160 mg/L or 7 mmol/L) or standard commercial infant formulas (160–185 mg/L or 7–8 mmol/L) [121]. Therefore, infants on PD are at risk of developing hyponatremia that can result in cerebral edema and blindness and must be maintained in neutral sodium balance; this is discussed further in ► Chap. 75, "Peritoneal Dialysis."

Potassium Potassium homeostasis in children with CKD is usually unaffected until the GFR falls to <10% of normal. However, children with renal dysplasia, post-obstructive kidney damage, reflux nephropathy, and renal insufficiency secondary to interstitial nephritis often demonstrate renal tubular resistance to aldosterone and may manifest hyperkalemia, even when their GFR is relatively well preserved. The hyperkalemia experienced by these children is exacerbated by volume contraction (and can be particularly common in salt losers) and the majority of the patients respond to salt and water repletion. In patients who are persistently hyperkalemic, dietary potassium intake should be limited. As potassium content is infrequently listed on food labels, a list of foods rich in potassium such as chocolates, French fries, potato chips, bananas, green leafy vegetables, dried fruits, and orange juice should be provided to patients and their families. Altering the methods of food preparation, such as soaking vegetables before cooking, helps decrease potassium content. Moderate to severe hyperkalemia may require treatment with a potassium binder such as sodium polystyrene sulfonate (SPS) (Kayexalate®), Patiromer (Veltassa®), or sodium zirconium cyclosilicate (SZC) (Lokelma®). In contrast to SPS that exchanges sodium for potassium ions and can also bind calcium and potentially result in hypocalcemia, Patiromer exchanges calcium for potassium ions, thus avoiding the provision of a sodium load and the possible inadvertent development of hypocalcemia. At present, Patiromer and SZC have only been approved for usage in adults and pediatric trials are ongoing.

In the case of infants and young children, special milk formulas such as Renastart® (Vitaflow USA) or Renalcal® (Nestle Health Sciences) are low in potassium and can be used to minimize exposure to dietary potassium (Table 6) [122].

Alternatively, the potassium content of formula can be reduced by pretreating it with a potassium binder, SPS, or Patiromer [123]. It is important to note that pretreatment of milk formula with SPS can reduce the calcium concentration by 8–29% and increase the sodium concentration by 86–300% [124].

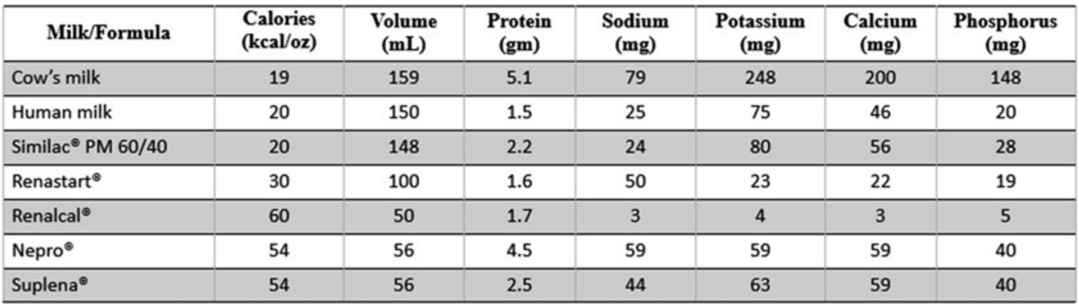
In children receiving maintenance HD, dietary potassium intake should be distributed throughout the day, as high serum concentrations of potassium can develop when a large quantity of potassium is ingested at one time, regardless of the total daily dietary content. On the other hand, some patients receiving PD may become hypokalemic due to potassium losses in dialysate and will require potassium supplementation, as hypokalemia has been associated with an increased risk for the development of peritonitis. Finally, constipation should be treated aggressively as significant quantities of potassium are eliminated through the gastrointestinal route in patients with CKD.

Vitamins and Micronutrients

Vitamins and minerals are essential for normal growth and development and either a deficiency or an excess can prove harmful. Unfortunately, the vitamin and mineral needs (other than for Vitamin D) of pediatric patients with CKD are not clearly defined, and the limited data that is available is derived from patients undergoing maintenance dialysis. Children with CKD are prone to develop vitamin deficiencies because of anorexia and dietary restrictions, while they are also at risk to develop toxic levels of vitamins when the renal clearance is significantly impaired.

All of the water-soluble vitamins except pyridoxine are eliminated by the kidneys and their clearance in patients with CKD is not known. However, most water-soluble vitamins are lost during maintenance dialysis and, in turn, should be routinely supplemented by special vitamin formulations that do not contain vitamin A and D, such as Nephronex® (L Lorens Pharmaceuticals), Nephro-Vite® (Allergan Inc.), and Dialyvite® (Hillestad Pharmaceuticals Inc.). Vitamin B_{12} and folic acid are both important for effective erythropoiesis, and daily supplementation with 0.8–1.0 mg folic acid is routinely recommended, while the necessity of vitamin B_{12} supplementation remains unsettled; this is discussed further in ▶ Chap. 73, “Anemia in Chronic Kidney Disease.” A higher dose of folic acid (2.5 mg per day) has been suggested by some for children with CKD and on dialysis, as supplemental folic

Table 6 Milk and selected commercial formula nutrient content per 100 kcal [122]



Milk/Formula	Calories (kcal/oz)	Volume (mL)	Protein (gm)	Sodium (mg)	Potassium (mg)	Calcium (mg)	Phosphorus (mg)
Cow's milk	19	159	5.1	79	248	200	148
Human milk	20	150	1.5	25	75	46	20
Similac® PM 60/40	20	148	2.2	24	80	56	28
Renastart®	30	100	1.6	50	23	22	19
Renalcal®	60	50	1.7	3	4	3	5
Nepro®	54	56	4.5	59	59	59	40
Suplena®	54	56	2.5	44	63	59	40

Conversion mg to mEq: sodium 23 mg = 1 mEq; potassium 39 mg = 1 mEq. Human milk electrolyte composition can vary with maternal diet. Renalcal® is a calorically dense, minimized electrolyte formula which should not be used as the only source of complete feeding acid has been shown to decrease the elevated homocysteine levels that are commonly seen in patients with CKD and that is a potential risk factor for cardiovascular morbidity and mortality [125].

Vitamin A levels are usually elevated in children with CKD as a result of the loss of the kidneys' normal ability to excrete vitamin A metabolites. Since elevated levels of vitamin A can be associated with the development of hypercalcemia and complications related to a high calcium-phosphorus product, it is important to avoid the use of vitamin supplements that include vitamin A.

Aluminum, copper, chromium, lead, strontium, tin, and silicon levels have all been noted to be elevated in patients with CKD, reflecting the fact that their clearance is dependent on an adequate GFR [126]. In contrast, zinc levels have been shown to be low in malnourished children and should be monitored and supplemented as necessary.

Current KDOQI pediatric nutrition guidelines [33] recommend the intake of at least 100% of the DRI for thiamin (B_1), riboflavin (B_2), niacin (B_3), pantothenic acid (B_5), pyridoxine (B_6), biotin (B_8), cobalamin (B_{12}), ascorbic acid (C), retinol (A), α-tocopherol (E), vitamin K, folic acid, copper, and zinc for children with CKD stages 2–5, and those receiving maintenance dialysis. In children older than 6 years of age undergoing PD, vitamin supplementation has been associated with normal or greater than normal serum levels of the water-soluble vitamins [127]. As most infant milk formulas including Similac PM 60/40 are fortified with both water-soluble and fat-soluble vitamins, most infants with CKD/ESKD receive the DRI/RDA for all vitamins (including vitamin A) by dietary intake alone.

Carnitine Carnitine is essential for normal mitochondrial function, fatty acid and energy metabolism, and cell membrane stability. Carnitine is essentially found in two forms in the body, as free carnitine and as acylcarnitines (compounds in which carnitine is bound, by acyl-binding, to fatty acids of varying size). While the serum total (sum of free carnitine and acylcarnitines), free, and acylcarnitine concentrations in the CKD patients are not different from the values in healthy individuals [128], in patients receiving HD, the serum free carnitine concentration is significantly lower because of increased removal during dialysis, and the serum acylcarnitine concentration is significantly greater due to decreased clearance; as a result, the ratio of acylcarnitine to free carnitine, an index of abnormal carnitine metabolism, is dramatically increased in patients receiving HD [128].

Carnitine deficiency can result in the development of anemia, cardiomyopathy, and muscle weakness [129]. However, there currently is insufficient evidence to support the routine use of carnitine in either the pediatric CKD or dialysis patient populations. However, a trial of supplemental carnitine may be indicated when all other causes for the symptoms in question have been excluded, carnitine deficiency has been confirmed, and the patient has been unresponsive to standard therapies [130]. Carnitine deficiency is reflected by an acyl: free carnitine ratio greater than 0.4 (i.e., [total – free carnitine] ÷ free carnitine) or a total serum carnitine value less than 40 μmol/L [129].

Nutrition Management

A registered dietitian with experience in pediatric kidney diseases should play the central role in the dietary management of children with CKD/ESKD. In addition to possessing knowledge related to nutritional requirements, this person should also be skilled in the evaluation of physical growth and the educational and social needs of this special population.

An individualized nutrition plan taking into account a variety of factors should be developed for each patient by the dietician in consultation with the physician, patient (when appropriate), and family, with clearly defined short- and long-term objectives. As cultural food preferences play an important role in the family's ability to adhere to dietary changes, dietary instructions should be tailored to help families modify, but not eliminate cultural food preferences. Background information on cultural diets and translated versions of renal diets and food lists are available for reference [131]. The plan should be modified as necessary according to changes in the child's nutritional status, kidney function, dialytic therapy, medication regimen, and psychosocial situation, with particular attention paid to any concerns for food insecurity.

Dietary restrictions should be limited as much as possible with a goal of enhancing nutrient intake. It is also important to find substitutes for restricted foods so as to maintain an adequate caloric intake. Adopting and maintaining changes in eating habits is also easier for a child if family members make similar changes, or at least avoid eating restricted foods in the child's presence. While the ideal goal is full compliance with the prescribed regimen, it is not always a realistic expectation and "partial compliance" is often acceptable. Being very rigid with the dietary prescription adds to parental stress and increases the risk for behavioral eating problems in the young child such as food refusal, gagging, and vomiting.

Oral Supplementation

Infants with CKD requiring fluid restriction or those who have a poor oral intake may require a greater caloric density of their milk formula than the standard 20 kcal/oz. The increase in caloric density should not be achieved by concentrating the milk formula, as this approach will also increase the protein and mineral content. The provision of extra calories can be achieved by adding carbohydrate and/or fat modules to the formula. Glucose polymers such as Polycose® (Abbott Nutrition) or SolCarb® (Medica Nutrition) have a low osmolality and are generally the initial supplements added to infant formulas. Additional calories can be added in the form of corn oil. Microlipid® (Nestle Nutrition), a 50% fat emulsion from safflower oil with 4.5 kcal/mL, and Duocal® (Nutrica North America), a fat and carbohydrate combo modular with 5 kcal per gram of powder, are commercially available products for energy supplementation. It is important to wait at least 24 h following each 2- to 4-kcal/oz incremental increase in concentration to enhance patient tolerance of the formula.

A variety of calorie-dense (1.8 kcal/mL) preparations such as Nepro® and Suplena® (Abbott Nutrition) have been formulated specifically for patients with kidney disease. Suplena® has a lower protein content than Nepro® (30 g/L vs. 70 g/L) and is preferable for pre-dialysis patients. These preparations are characterized by a low renal osmolar load and a low vitamin A and D content. Although initially produced for patients older than 10 years, they have been used in children as young as 3 years; however, it is advisable to dilute them to half to two-third strength when used in young children.

In contrast to energy intake, the protein requirements of children with CKD are usually met by voluntary, unsupplemented consumption. A recently published CKiD experience revealed that the median dietary protein intake of children with CKD exceeded recommended levels in all age groups, particularly among younger subjects [83]. However, if on occasion the protein intake is insufficient due to concomitant phosphorus restriction in a patient with severely impaired kidney function, the protein module, Beneprotein® (Nestle Nutrition), a whey protein concentrate, can be added to the formula to increase protein content. As much as 1 gm of Beneprotein®, which is equivalent to 0.86 gm protein, can be added to each ounce of formula.

Enteral Nutritional Support

Aggressive enteral feeding should be considered if nutritional intake by the oral route is suboptimal. The use of enteral support has resulted in maintenance or improvement of SD scores for weight and/or height in infants and young children with moderate to severe CKD and those undergoing maintenance dialysis [85, 86, 132].

Nasogastric (NG) tubes, gastrostomy tubes, gastrostomy buttons, and gastrojejunostomy tubes have all been used to provide supplemental enteral feeding to children with kidney disease [133]. A study from the IPPN registry, however, revealed that tube feeding was predominantly used in North America and Europe, with very little usage elsewhere in the world [85] [86]. The tube feeding can be given as an intermittent bolus, or more commonly by continuous infusion during the night. Continuous overnight feeds are generally preferred to allow time during the day for regular oral intake. Historically, the NG tube was used most frequently in infants and young children, as it is easily inserted and is generally well tolerated [132]. However, this route of therapy is often complicated by recurrent emesis and the need for frequent tube replacement, in addition to the risk of pulmonary aspiration, nasoseptal erosion, and psychological distress of the caretaker because of the cosmetic appearance. An NG tube is, however, the preferred option for short-term enteral feeding, and may be considered as a bridging option to a long-term enteral feeding tube. Persistent emesis can be addressed by slowing the rate of formula delivery and by the addition of antiemetic agents such as metoclopramide or domperidol. Additionally, whey-predominant formulas can be used as they have been shown to stimulate gastric emptying [134].

The gastrostomy tube or button is now considered the standard approach to long-term enteral feeding. It has the cosmetic advantage of being hidden beneath clothing. The reported complications of gastrostomy tubes/buttons include exit-site infection, leakage, obstruction, gastrocutaneous fistula, and peritonitis in patients receiving PD [135]. To decrease the risk of peritonitis, the gastrostomy should be placed either before or simultaneously during PD catheter placement, accompanied by antibiotic and antifungal prophylaxis [33, 136]. In addition, it may be better to avoid combining gastrostomy placement and peritoneal dialysis catheter placement in a severely malnourished patient until the nutritional status and general immunity of the patient can be improved by other means, such as NG tube feeds.

Transpyloric tubes are recommended only in circumstances of severe gastroesophageal reflux, gastroparesis, or gastric outflow obstruction. Positioning of the tube within the jejunum requires radiological guidance. As boluses entering the jejunum are poorly tolerated, both gastro-jejunal and naso-jejunal tubes require that all formula delivery is by continuous infusion.

A common and serious complication of using any form of enteral tube feeding is a prolonged and potentially difficult transition from tube to oral feeding. Regular non-nutritive sucking and repetitive oral stimulation are recommended for all tube-fed infants.

Growth Hormone-Insulin Growth Factor (IGF)-I in CKD

Growth hormone (GH) is a 22-kD protein which is filtered by the glomerulus and plasma levels increase as kidney function worsens due to increased secretion and reduced clearance of GH. GH acts via the GH receptor to stimulate the synthesis of insulin growth factor-1 (IGF-I) at growth plate cartilage and in the liver from where it is liberated into the circulation. Despite normal IGF-I levels in children with CKD, IGF-I synthesis and bioactivity are decreased in CKD and this fact provides the rationale for recombinant human growth hormone (rhGH) therapy. The impact of CKD on growth hormone receptor density, growth hormone function, and subsequent growth is not clear. Some studies demonstrate a lower density of GH receptors in the liver and reduced hepatic GH receptors have been demonstrated in animal studies [137]. Another proposed mechanism for GH and IGF-I resistance is a post-receptor GH signaling defect which has been repeatedly observed in key tissues of CKD rats [16]. Signal transduction following GH binding to its receptor requires the activation of JAK2, which in turn stimulates tyrosine kinase to phosphorylate STAT1, STAT3, and STAT5. As soon as these are phosphorylated, they form dimers which pass into the nucleus, activating genes that generate IGF-I. Impaired JAK2–STAT5 phosphorylation has been demonstrated to play a part in GH resistance and growth failure in CKD rats [16]. Another family of proteins, SOCS, contributes to the GH signaling as upregulated SOCS dephosphorylate STAT, leading to a negative feedback action of GH in CKD [16]. CKD patients also exhibit reduced levels of circulating growth hormone–binding protein (GHBP). Higher GHBP levels are associated with improved growth patterns and with a positive response to rhGH treatment in pediatric CKD [137].

Other mechanisms for GH resistance in CKD include effects on IGF-I activity. Serum total IGF-I levels in children with mild to moderate CKD are adequate, but are decreased in those with ESKD. In addition, as CKD progresses the level of free IGF-I is diminished and IGF-I activity decreases [138]. This discrepancy is attributed to increased levels of IGF-binding proteins due to decreased kidney clearance in CKD leading to a decrease in the active form of IGF-I (Fig. 3) [138–141].

Chronic metabolic acidosis negatively impacts growth in children with CKD as well, through alterations in the GH–IGF-I axis and response to IGF-I [141]. Several studies have shown that acidotic rats grew less and had a significantly smaller size of the tibial epiphyseal growth plates compared with matched controls. These data indicate that metabolic acidosis induces resistance to IGF-I

Growth Hormone Therapy in Pediatric CKD

In pediatric CKD patients, the resistance to GH can be overcome by supraphysiologic doses of rhGH that significantly enhance growth velocity and potentially result in a more normal adult height [143]. Numerous studies have shown the safety and efficacy of rhGH in pediatric CKD, even after kidney transplantation [144]. A Cochrane review which included 16 controlled trials of rhGH therapy in 809 pediatric patients in various stages of CKD showed that children who received 1 year of rhGH had a higher average HtSDS and height velocity as compared with controls, and that rhGH therapy significantly improved HtSDS and height velocity in this population [145].

A recent consensus statement from the European Society for Pediatric Nephrology CKD Working Group recommended rhGH treatment in pediatric CKD for patients with a HtSDS <3rd percentile or with a height velocity < -2 SD. The consensus statement warns that rhGH therapy should be started only after other contributing factors to growth failure have been appropriately managed, including treatment of anemia and infections, correction of nutritional deficiencies, and optimization of CKD-MBD management [146]. The KDOQI nutritional guidelines recommend that rhGH should be considered if catch-up growth has not been triggered after 3 months of appropriate nutritional management [33].

Administration of 28–30 IU rhGH/m^2 per week or 0.05 mg/kg/day seems to be the optimal dose in most studies. A doubling of this dose did not result in significant improvement in the growth of transplanted patients. Several studies have indicated a more robust response to rhGH in prepubertal children than during adolescence. The improvement of growth was negatively correlated with patient height at treatment initiation, and the most stunted patients responded best to rhGH treatment. Another important factor which influences the growth response is the primary renal disorder. Children with renal hypo/dysplasia, which is by far the most frequent primary renal disease leading to CKD in children, responded better than children with glomerulonephritis or other renal disorders [147]. Finally, a study including 836 adult or near-adult patients on various modalities of maintenance dialysis who received rhGH during childhood for at least 2 years showed a median absolute increase in height of 7.4 cm in boys and 7.0 cm in girls [143].

Several randomized controlled trials and observational studies have shown that while rhGH is safe and well tolerated, long-term follow-up data are still lacking. Potential adverse effects include increased intracranial hypertension, increased incidence of malignancy, slipped capital femoral epiphyses (SCFE), avascular necrosis, glucose intolerance, pancreatitis, allograft rejection, and fluid retention. Whereas a Cochrane review showed that the prevalence of adverse events related to use of rhGH was usually similar in the intervention and control groups, screening and monitoring for these side effects remains important (Table 7) [145, 146].

Table 7 Recommended monitoring in CKD patients receiving rhGH therapy

Baseline fundoscopic exam due to concern for risk of increased intracranial pressure
Glucose intolerance, especially in patients with nephropathic cystinosis who are at higher risk for diabetes
Secondary hyperparathyroidism which may be accelerated or discovered during GH treatment. Withhold rhGH if iPTH is >500 pg/mL
SCFE, which is more likely to occur during periods of rapid growth and if iPTH >500 pg/mL. X rays should be obtained if symptoms develop
Renal disease progression
Bone and sexual maturation with Tanner staging and annual wrist radiographs
Growth response; discontinue use if inadequate response after 6 months, renal transplantation, patient attains genetic height or epiphyseal growth plate closure is evident on radiographs

Although its safety and effectiveness are well established, rhGH remains an underutilized treatment option. There is considerable variation in pediatric nephrology practices in addressing growth failure with rhGH use in children with CKD, and patient nonadherence to rhGH therapy as a result of the need for daily injections is frequent [148]. In the CKiD study, the rhGH nonadherence rate was about 18% and, as expected, nonadherence to rhGH was associated with poorer growth velocity, indicating a possible window of opportunity for an intervention to improve CKD patient outcome [149].

Neurocognitive Development

Brain development is most rapid during early childhood, and thus the developing brain is at greatest risk for injury during infancy and early childhood [150]. In turn, several studies have suggested that there is an increased risk for developmental delay in children with early onset CKD or ESKD [151, 152].

There are a number of factors associated with impaired kidney function that may contribute to impaired neurocognition. In addition to the potential direct adverse effects of metabolic neuronal toxicity, vascular injury and endothelial dysfunction, malnutrition, aluminum toxicity, and psychosocial deprivation have all been associated with neurocognitive dysfunction in children with CKD and ESKD [153]. Thankfully, recognition of the adverse impact of the latter three factors have led to alterations in patient management so as to ideally minimize or even eliminate their influence on neurocognition [49, 154].

Early studies of neurodevelopment in children with CKD/ESKD, at a time when the connection between malnutrition, aluminum intoxication, and potentially dialysis adequacy with neurocognition was less recognized, provided evidence of severe delays in subjects both on and not yet on dialysis [155]. While the published studies were characterized by small sample sizes, and patients of a wide age range and receiving a variety of different treatment regimens, delays in gross motor function and language and lower IQ scores were well documented, as was the presence of microcephaly in the youngest patients [156]. Older children and adolescents have also demonstrated significantly lower IQ scores compared to controls, with evidence of poorer abilities in gross and fine motor coordination, visuomotor skills, verbal abilities, attention, and short-term memory, the latter deficit being greatest in those children on dialysis [155, 157]. Some, but not all, studies have also revealed abnormalities of executive function, as well as problems in academic achievement as reflected by difficulties with reading, spelling, and math, all of which are associated with increased school absences and more frequent grade retention [158]. In addition, these issues may translate into lower verbal and nonverbal capacities and executive dysfunction in adulthood. Electrical conduction dysfunction with EEG abnormalities have also been reported in children with CKD from infancy, abnormalities which may contribute to the development of a seizure disorder, a complication noted in 0–20% of children with ESKD. While the receipt of a kidney transplant has repeatedly been shown to be associated with improvements in cognitive function, most beneficial to long-term neurocognitive outcome appears to be a shorter duration of dialysis during childhood and older age at the time of renal replacement therapy [159, 160].

Most important to the management of children with CKD/ESKD from the neurocognitive perspective is regular surveillance by the medical team, in concert with the child's family, with recognition of the increased risk that exists for neurodevelopmental challenges. If detected, the institution of developmentally appropriate interventions designed to optimize the child's cognitive trajectory should be carried out, in addition to the necessary medical interventions, and coordinated by a multidisciplinary team which includes representatives from nephrology and psychology at a minimum, with other resources (e.g., neurology, physical/occupational therapy, etc.) as deemed appropriate.

Abstract

Chronic kidney disease mineral and bone disorder (CKD-MBD) is a systemic disorder that encompasses alterations in mineral homeostasis, bone turnover, mineralization, volume and strength, linear growth and strength, and cardiovascular disease. CKD-MBD in childhood may lead to significant bone pain, deformities, and fractures that hinder the daily activities and quality of life of children with advanced CKD; these sequelae persist into adulthood whereas many as 18% of this population reported disabilities resulting from their bone disease. Children with CKD, especially those on dialysis, have a greatly increased risk of cardiovascular (CV) morbidity and mortality; vascular calcifications are present in even children and young adults with end-stage kidney disease (ESKD). Management of CKD-MBD requires attention to long-term skeletal and cardiovascular health. Clinical evaluation of height, growth velocity, blood pressure and a musculoskeletal examination, focusing on bone pain, deformities, and fractures, should be performed routinely in children with CKD; dietary calcium (Ca) and phosphate (P) intake should also be assessed at regular intervals. P-binders and vitamin D analogs should be used to treat secondary hyperparathyroidism in children with advanced CKD. Age-, gender-, and CKD stage- appropriate values of Ca, P, alkaline phosphatase, and PTH should be used to guide therapy.

Introduction: CKD-MBD in Pediatrics

Chronic kidney disease mineral and bone disorder (CKD-MBD) is a systemic disorder that encompasses alterations in mineral ion homeostasis, in bone turnover, mineralization, volume and strength, linear growth and strength, and cardiovascular disease [1]. This chapter describes the epidemiology, pathophysiology, and treatment of these alterations in children with all stages of CKD and a variety of CKD etiologies.

Epidemiology

Skeletal symptoms, including limb deformities, bone pains and fractures, or radiological signs of bone disease have been reported in 15% of children on peritoneal dialysis [2]. This number likely underestimates the true prevalence of clinical bone disease in childhood CKD, and a recent study reported that significant bone pain hindered the daily activities of 58% of children with advanced (i.e., stages 4–5) CKD [3]. In large prospective studies of children with CKD, including the North-American Chronic Kidney Disease in Childhood (CKiD) cohort, a 2.4- and 3-fold higher rate of fractures have been reported in boys and girls (respectively) with pre-dialysis CKD as compared to healthy children [4]. Fracture risk in pediatric CKD is associated with baseline-walking difficulty, more advanced (Tanner stages 4–5) pubertal development, lower height Z-score, higher parathyroid hormone (PTH) levels, lower Ca and 25-hydroxyvitamin D (25D) levels and team sports participation [4]. Phosphate binder (P-binder) use (and particularly Ca-based P-binders) have been associated with decreased fracture risk in children with pre-dialysis CKD, suggesting that improved P control and/or increased calcium intake may exert some protective benefit [70]. Importantly, CKD-MBD in childhood leads to important sequelae in adulthood, with 37% of Dutch adults who developed end-stage kidney disease (ESKD) before 14 years of age reporting severe bone disease (defined by bone deformities, chronic pain, low-trauma fracture, and/or aseptic necrosis) and 61% reporting severely decreased final adult height. As many as 18% of this population reported disabilities resulting from their bone disease [4].

In addition to skeletal disease, children with CKD, especially those on dialysis, have a 10-fold increase in cardiovascular (CV) morbidity and mortality; vascular calcifications are present in even children and young adults with ESKD [5–7].

Pathophysiology of CKD-MBD

A complex interplay between kidney, gut, bone, and parathyroid glands drives the pathogenesis of CKD-MBD. As glomerular filtration rate (GFR) declines, a cascade of maladaptive events ensue that result in bone disease, extra-skeletal calcification, and adverse cardiovascular outcomes as well as impaired quality of life and decreased life expectancy. Disordered regulation of Ca and P, increasing skeletal resistance to the actions of PTH, an impaired growth hormone – insulin-like growth factor 1 (GH/IGF1) axis, malnutrition (either under- or over-nutrition), iron deficiency, acidosis, uremic toxins, altered signaling in pathways driving bone and vascular biology (e.g., receptor activator of nuclear factor kappa-B [RANK] and RANK-ligand [RANKL], bone morphogenic protein [BMP]; runt-related transcription factors [RUNX] and wingless and integrin 1 [WNT], etc.), and underlying genetic mutations directly affect both bone and vessels. In addition, the therapies used to treat CKD-MBD affect not only mineral ion homeostasis but osteoblast/osteoclast/osteocyte cross-talk in bone and vascular smooth muscle cell biology (Fig. 1).

Bone consists primarily of Ca and P, in the form of hydroxyapatite; thus, the alterations in mineral metabolism that occur with progressive CKD lead to bone disease. While bone is the major reservoir for P and Ca ions, hormones derived from bone cells, the parathyroid glands, and renal proximal tubular cells (i.e., fibroblast growth factor 23 [FGF23]; parathyroid hormone [PTH]; and 1,25-dihydroxyvitaminD [1,25D], respectively) all regulate Ca and P homeostasis. Circulating FGF23 levels increase in very early CKD, due to decreased renal FGF23 clearance, an early decline in renal Klotho (a critical FGF23 co-factor in most tissues), and CKD-mediated changes in bone biology which stimulate skeletal FGF23 expression [8]. Regardless of its primary cause, increased circulating FGF23 levels suppress renal 1α-hydroxylase activity, causing 1,25D levels to fall in even early CKD stages. Decreased 1,25D levels in turn reduce intestinal Ca absorption. The combination of low 1,25D and low ionized Ca levels stimulate PTH release from the parathyroids, resulting in secondary hyperparathyroidism. Approximately 50–60% of patients with late CKD stages (CKD stages 4 and 5) develop hypocalcemia in response to the decreased intestinal Ca absorption that develops from critically low calcitriol concentrations; decreased P excretion (from critically low renal mass) contributes to hyperphosphatemia in these patients with severe CKD [9]. In addition, 25D deficiency, which is prevalent worldwide, also contributes to the development of secondary

DECREASED QUALITY OF LIFE and LIFE EXPECTANCY

Fig. 1 **Overview of pediatric CKD-MBD**. The reduction in nephron number decreases both P reabsorption and renal 1-alpha hydroxylation of vitamin D, thus inducing hyperphosphatemia, decreased 1–25 $(OH)_2$ levels and subsequent hypocalcemia. All these factors increase PTH levels, with the development of secondary hyperparathyroidism. Dysregulated mineral metabolism is central to the vasculopathy and bone disease of CKD but additional factors worsen this (already complex) CKD-MBD setting, as illustrated around the elementary and fundamental factors explaining the pathophysiology of CKD-MBD. *OB/OC/OCy* osteoblast/osteoclast/osteocyte, *rhGH* recombinant human growth hormone, *cIMT* carotid intima/media thickness

hyperparathyroidism; a placebo-controlled randomized trial in children with pre-dialysis CKD demonstrated that ergocalciferol therapy is able to delay the onset of secondary hyperparathyroidism in this population [10]. Although data from the CKiD population suggest that increased P load is not an important driver for early increases in FGF23, a decline in circulating P concentrations can be observed in very early CKD when circulating FGF23 levels and bone FGF23 expression are increased [11]; hyperphosphatemia does contribute to increased FGF23 in late CKD. In later stages of CKD, treatment with active vitamin D analogs further contribute to increasing FGF23 levels. Non-mineral metabolism factors such as iron status, erythropoietin, and inflammation may also contribute to increased FGF23 production in all CKD stages. In murine models, both absolute and “functional” iron deficiency increase bone FGF23 expression [12]. Erythropoietin can also stimulate FGF23 production and, conversely, FGF23 may suppress erythropoiesis [13]. FGF23 levels are higher in patients with glomerular diseases when compared to those with congenital anomalies of the kidneys and urinary tract (CAKUT) [14]; inflammation increases bone and circulating FGF23 levels [12].

Normal Bone Development

Bone Structure

Bone provides structure and support for the body, protecting organs and providing levers for movement. Bone also acts as a reservoir for the storage and release of chemicals such as Ca and P that are critical for cellular function. In addition, bone acts as an endocrine organ, making and secreting factors that act locally, on its own cells [15] as well as on distant organs that regulate mineral ion homeostasis [16] and energy metabolism [17].

Bone tissue is woven into two main patterns: cortical and cancellous bone. Cortical bone is the major component of the long bones in the appendicular skeleton but also surrounds the exterior portion of bones in the axial skeleton. Cancellous bone is the internal tissue of skeletal bone which is found at the ends of long bones, near joints, and in the interior of vertebrae and comprises 20% of total bone mass in adults. Cancellous bone is more metabolically active than is cortical bone, accepting mineral ions from, and releasing them to, the circulation in response to hormonal stimuli [18].

As early as weeks 3–4 of embryonic development, somites form from the paraxial mesoderm, establishing the axial body structure. Most of the skeleton (including the vertebrae and the limb long bones) is formed by endochondral ossification in which an initial cartilage template is replaced by calcified bone (Fig. 2) [19]. Osteoblasts derived from chondrocytes and from mesenchymal cell within the bone collar replace cartilage matrix with a matrix rich in type I collagen. This collagen serves as a nidus for Ca and P – in the form of hydroxyapatite – accumulation. Intramembranous bone formation is critical for the patterning and ossification of the skull and clavicle. In this form of bone development, neural crest-derived mesenchymal cells proliferate and differentiate into osteoblasts, which secrete collagen-proteoglycan matrix that can bind Ca salts and vascular cells [20]. Skeletal patterning is complete and the basic shapes of all bones are established by 9 weeks postconception [21]. After this time, the skeletal matrix accumulates mineral (ossifies) and grows, but does not change its basic external shape.

Growth of long bones involves lengthening and also an increase in diameter. Lengthening involves growth followed by osteoblastic transition and ossification of chondrocytes in epiphyseal cartilage [22] while bone widening requires the apposition of tissue to the external surface by osteogenic cells in the periosteum. During bone modeling, the internal structure of bone is modified; trabecular thickness increases by about 30% during the second half of gestation while cortical thickness at the mid-shaft doubles [23]. After birth, periosteal bone formation and endosteal bone lengthening both continue. In adulthood, cyclical episodes of periosteal bone formation are coupled to episodes of bone resorption in the process of bone remodeling; however, periosteal bone apposition exceeds bone resorption in children (i.e., bone modeling) [24].

Fig. 2 **Endochondral bone formation:** (1) a matrix template.is created by chondrocytes which (**a**) proliferate. With time, chondrocytes condense and hypertrophy (**b**); A bone collar is formed and invaded by nutrient vessels. Bone growth (**c**) occurs by continued proliferation/hypertrophy/ossification at the ends of the bones (longitudinal growth) and by periosteal bone formation (periosteal/lateral growth). (**d**) Mature long bone is composed of a compact outer structure (cortical bone) and a cancellous (trabecular) inner structures of rods and plates

Role of Different Cell Types in Bone Structure and Function

Active remodeling of bone occurs throughout life through cross-talk between osteoblasts, which lay down bone matrix, and osteoclasts, which erode mature, mineralized bone. The function of both cell types is regulated by osteocytes embedded within mineralized bone. These coordinating signals create a tight feedback loop of bone formation and resorption in vivo*,* termed “coupling” [25].

Paracrine and Endocrine Functions of Bone Cells

Osteoblasts, osteocytes, and osteoclasts secrete proteins that regulate bone formation and remodeling in a local (paracrine) manner. Osteoblasts and osteocytes also have classic endocrine functions, secreting hormones which act on distal organs. Mature osteoblasts secrete large amounts of the non-collagenous protein osteocalcin (OCN; BGLAP), which is a major determinant of bone formation [26], and which also regulates metabolism in many tissues, increasing energy expenditure and reducing fat mass, improving insulin sensitivity, and preventing liver steatosis [27]. Osteocytes also have an important endocrine function, secreting FGF23 [28]. Although the factors that regulate osteocyte function are poorly defined, circulating mineral ions, such as P, PTH, and 1,25(OH)$_2$vitamin D, stimulate FGF23 expression. The stage of osteocyte maturation also appears to be critical in their function; FGF23 appears to be expressed almost exclusively in early osteocytes [8], while the Wnt-signaling inhibitor sclerostin is confined to the most mature osteocytes in bone [29].

Renal Bone Disease

Renal bone disease is a common complication of CKD and is nearly universal at the start of dialysis therapy. While the term “CKD Mineral and Bone Disorder” (“CKD-MBD”), refers to the alterations in mineral metabolism and their effects on both the cardiovascular and skeletal systems in the CKD population, the term “Renal osteodystrophy” is used specifically to describe the bone pathology that occurs as a complication of CKD [30]. On bone histology, renal osteodystrophy lesions are defined according to alterations in bone turnover, ranging from high bone turnover (secondary hyperparathyroidism, osteitis fibrosa) to lesions of low bone turnover (adynamic bone disease and osteomalacia). However, alterations in skeletal mineralization and volume are also common in pediatric CKD patients [31], and may contribute to outcomes such as fractures, skeletal deformities, and poor growth which persist despite normalization of bone turnover [4]. Each of these parameters is affected by circulating PTH, Ca, P, 25(OH) vitamin D, and FGF23 levels and also by renal osteodystrophy therapies [30]. However, as previously mentioned, uremia itself alters bone cell biology contributing to features such as PTH resistance and intrinsic mineralization defects [8]. These features limit the reliability of currently available biomarkers to predict underlying bone histology (Fig. 3).

The Bone Biopsy Procedure

Although iliac crest bone biopsy is an invasive procedure which is not universally performed, bone histomorphometry remains the gold standard for the diagnosis of different types of bone diseases associated with CKD [32]. Bone histomorphometry provides information about the histologic appearance and dynamics of bone formation and mineralization and can also inform the clinician on the accumulation of substances such as aluminum, oxalate, iron, and amyloid in bone. While not routinely recommended, a bone biopsy may be considered in all patients with CKD who have fractures with minimal trauma (pathological fractures), suspected aluminum

Fig. 3 Renal bone disease (renal osteodystrophy) comprises a spectrum of turnover, mineralization, and volume lesions. Untreated secondary hyperparathyroidism and medications such as calcineurin inhibitors promote high bone turnover, characterized by increased cellular activity and poorly organized bone matrix. Oversuppression of PTH with vitamin D sterols and calcium-based phosphate binders can lead to low bone turnover, which is characterized by highly mineralized bone with low cellular activity. Mineralization defects are common in CKD patients and are exacerbated by the direct effects of uremic toxins on osteoblast maturation and the overuse of phosphate binders

bone disease, or persistent hypercalcemia despite well-controlled PTH levels. Before the procedure, bone is labeled with tetracycline in order to evaluate bone turnover. A 2-day course of tetracycline is administered at 15 mg/kg/day (divided in twice or thrice daily doses). Fourteen days later, the 2-day course is repeated. For children younger than 8 years, tetracycline dosage is usually kept below 10 mg/kg/day to avoid toxicity.

Turnover

Abnormalities in bone turnover, driven by circulating PTH concentrations, are prevalent in children with advanced stages of CKD. PTH activates the PTH/PTHrP receptor on osteocytes and osteoblasts, thereby directly increasing the cellular activity of osteoblasts and, indirectly, the activity of osteoclasts [33]. Skeletal resistance to PTH develops as CKD progresses, due to multiple factors including, although likely not limited to the accumulation of circulating PTH fragments [34] and downregulation of the PTH receptor [35], complicating the interpretation of serum PTH levels in the assessment of bone formation rates. Prolonged exposure to elevated PTH levels and increases in bone turnover may lead to peritrabecular fibrous changes in bones; thus, the renal osteodystrophy associated with prolonged secondary hyperparathyroidism is often termed "osteitis fibrosa cystica." A state of low-turnover bone disease (adynamic renal osteodystrophy) defined as decreased bone formation rate in conjunction with decreased cellular activity and an absence of excessive osteoid accumulation may occur in children treated with maintenance dialysis who receive overaggressive therapy with active vitamin D sterols and Ca salts. In addition to the increased risk for fractures and vascular calcifications that is observed in adults with adynamic bone, this form of bone disease in children treated with dialysis is associated with a further decline in growth [36].

Although bone turnover is undoubtedly affected by changes in circulating PTH in advanced CKD, recent data from animals and humans have suggested that changes in bone turnover occur before alterations in circulating mineral, PTH, or vitamin D concentrations are apparent [31]. These changes are mediated, at least in part, by impaired osteoblast and osteocyte maturation [8] and by the increased expression of the osteocyte-specific Wnt-signaling inhibitor sclerostin [37] in all CKD stages.

Mineralization

Alterations in skeletal mineralization are also prevalent in children with CKD [31] and may be seen in children with early CKD, prior to the onset of secondary hyperparathyroidism. Defective mineralization appears to be the first detectably histologic lesion in children with CKD, affecting up to 40% of children with CKD stage 2 and as many as 80% of those with more advanced stages of CKD [31]. These lesions persist in children treated with maintenance dialysis and are not corrected by therapy with active vitamin D sterols [38].

Defective skeletal mineralization is associated with increases in unmineralized bone (osteoid) in conjunction with delayed rates of mineral deposition. In the face of low to normal bone turnover, defective mineralization in growing children is termed "rickets." The histomorphometric characteristics of rickets include the presence of wide osteoid seams, an increased number of osteoid lamellae, an increase in the trabecular surface covered with osteoid, and a diminished rate of mineralization or bone formation, as assessed by double tetracycline labeling. Fibrosis is absent. Defective mineralization in combination with increased bone formation rates is termed "mixed uremic osteodystrophy" and is characterized by wide osteoid seams, prolonged mineralization times, bone marrow fibrosis, and increased bone formation rates [30].

Although the mechanisms of skeletal mineralization are incompletely understood, factors such as 25(OH)vitamin D (25D) deficiency and altered FGF23 metabolism have been implicated in their pathogenesis. In the general population, nutritional 25D deficiency results in osteomalacia and a similar phenotype may occur in patients with

CKD. P depletion, as may occur with frequent dialysis and/or intensive use of P-binders, may also result in osteomalacia. FGF23 may also play a role; both overexpression [39] and ablation of FGF23 [28] in mice with normal renal function are associated with abnormal mineralization of osteoid, although by different mechanisms. The phosphaturic effect of increased FGF23 may cause rickets and osteomalacia through an insufficiency of mineral substrate. Osteomalacia in animals with FGF23 deficiency suggests that FGF23 may play a direct role in skeletal mineral deposition. Recent data suggest that factors that impair bone cell maturation also contribute to skeletal mineralization defects in pediatric CKD patients [8]. Elevated serum PTH levels are associated with mineralization defects in children with CKD, independent of abnormalities in bone turnover [31] and PTH plays an important role in osteocyte maturation [40]. While the ramifications of defective mineralization remain to be established, increased fracture rates and bone deformities are prevalent in patients with CKD despite adequate control of bone turnover [4]. These complications may be due, in part, to alterations in bone mineralization.

Volume

Since PTH is anabolic at the level of trabecular bone, high levels of serum PTH are typically associated with increases in bone volume, trabecular volume, and trabecular width. However, bone volume may also be low (termed “osteoporosis”) particularly in individuals with underlying age-related bone loss or in those treated with corticosteroids. Low bone volume is rare in the pediatric CKD population [41].

Linear Growth

Growth retardation is the hallmark of CKD in children. Growth failure worsens as renal function declines; the average height of children with even mild CKD (GFR 50–70 mL/minute/1.73 m^2) is 1 standard deviation (SD) below the average for healthy children. Moderate CKD (GFR 25 to 49 mL/minute/1.73 m^2) is associated with a height SD of –1.5, and, at the time of initiation of dialysis, the mean height SD is –1.8. Acidosis, calcitriol deficiency, secondary hyperparathyroidism, and adynamic osteodystrophy all may contribute to growth retardation. Treatment for secondary hyperparathyroidism with large, intermittent doses of calcitriol and Ca-based P-binders may decrease linear growth velocity due to dose-dependent inhibitory effects of calcitriol on cell proliferation of chondrocytes and osteoblasts in vitro and to increased expression of IGF-binding proteins [42]. Growth failure persists in many patients despite the correction of the metabolic abnormalities, however, and GH resistance is a major contributor to impaired linear growth in children with even mild kidney disease [43]; further details are discussed in ▶ Chap. 71, “Nutrition, Growth, and Development.”

Interaction Between Primary Kidney Disease and Renal Bone Disease

Rare inherited kidney diseases have recently demonstrated that an element of bone disease may be due to specific mutations – independent of the degree of kidney failure and CKD-MBD – in a subset of children with CKD. Exacerbated skeletal disease is prevalent in patients with primary ciliopathies [44] and those with underlying storage diseases. Ongoing research continues to investigate the interaction between genetics and bone disease in all children with kidney disease.

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is among the most common hereditary nephropathies. Low bone turnover osteopenia characterizes mice with conditional deletion of *PKD1* or *PKD2* genes in osteoblasts, and adults with ADPKD characteristically display low bone turnover, low alkaline phosphatase levels, increased FGF23 levels, and significant hypophosphatemia [45].

Primary Hyperoxaluria

Primary hyperoxaluria is an autosomal recessive defect with a direct deleterious effect on bone. Since bone can store massive amounts of oxalate, patients often present with recurrent low-trauma fractures, bone deformities, and severe bone pain. Calcium oxalate (whewellite) deposits accumulate in the bone marrow space, but not in the bone matrix itself. A granulomatous reaction accompanies this deposition. Overall bone is more brittle than normal [46]. Clinical bone disease worsens in patients treated with dialysis since even intensive hemodialysis regimens remove far less oxalate than is endogenously produced and circulating concentrations of oxalate universally exceed maximum soluble concentrations in patients treated with intensive maintenance dialysis.

Cystinosis

Cystinosis is an autosomal recessive lysosomal storage disease characterized by a deficiency of the cystine lysosomal transport protein (i.e., cystinosin), which results in the systemic accumulation of cystine crystals in many tissues. Cystinotic patients suffer from complete proximal tubulopathy with acidosis and profound hypophosphatemia (Fanconi syndrome) in early childhood; 95% of children have short stature, osteopenia, and rickets. Progressive chronic interstitial nephritis leads to ESKD; secondary hyperparathyroid uremic bone disease thus contributes to bone disease later in the first or second decade of life. In addition, in vitro experiments demonstrate that cystinosin deficiency in bone cells leads to a bone loss phenotype, independent of renal failure. Finally, although cysteamine therapy increases patient and renal survival and decreases systemic comorbidities, cysteamine also affects bone cell function. Low doses of cysteamine have antiresorptive effects and stimulate osteoblastic differentiation and mineralization; by contrast, high doses inhibit osteoblast differentiation in vitro [47]. Thus, the primary disease and its treatment interact with renal P wasting and progressive renal disease to create particularly fragile bone quality in this population (see ► Chap. 37, “Cystinosis”).

Other Genetic Syndromes

Data are limited on the impact of other genetic diseases on bone in children with CKD; however, the role of primary cilia in conditions such as nephronophthisis suggest that patients with mutations in *NPHP6*, *MKS1*, or *MKS3* may have bone pathology that is independent of kidney failure [48]. In addition, the skeletal disease in Pierson syndrome may be exacerbated by the absence of laminin-β2 in bone [49]. In the future, understanding the impact of the different genetic defects on the growing skeleton will likely lead to targeted therapeutic strategies.

Bone Disease After Successful Kidney Transplantation

Successful kidney transplantation corrects many of the bone abnormalities associated with CKD, but disorders of bone and mineral metabolism remain a major problem in the transplant population. Several factors, including persistent secondary hyperparathyroidism, prolonged immobilization, and delayed/poor graft function may negatively affect bone health. Various immunosuppressive agents have also been implicated in the development of bone disease after organ transplantation. Significant bone loss has been shown to occur as early as 3–6 months after kidney transplantation [50].

In both adult and pediatric kidney recipients, iliac crest bone histologic changes associated with secondary hyperparathyroidism resolve within 6 months after kidney transplantation; bone mineral content Z-scores, however, remain significantly reduced, especially in cortical bone [51]. Interestingly, a disconnect is observed between circulating PTH levels and bone turnover posttransplantation; some patients have persistently elevated rates of bone turnover while others develop adynamic lesions, despite moderately elevated serum PTH levels [52]. The use of maintenance corticosteroids may play a causal role; steroids decrease intestinal Ca absorption, enhance urinary Ca excretion, inhibit osteoblastic activity, decrease bone formation, and increase osteoclastic activity and bone resorption [53]. Azathioprine has a minimal impact on skeletal remodeling and the role of other immunosuppressive agents, such as mycophenolate mofetil, as potential modifiers of bone formation and bone resorption have not been evaluated.

After successful kidney transplantation with immunosuppressive regimens standard in many institutions (daily corticosteroids, calcineurin inhibitors, and/or antimetabolites), growth may be accelerated by an improvement in kidney function, but catch-up growth may not be observed even in children who undergo transplantation very early in life [54]. The cause of persistent growth retardation is not completely understood, but immunosuppressive agents, persistent secondary hyperparathyroidism, altered vitamin D and FGF23 metabolism, and the persistence of defective skeletal mineralization may all contribute. Use of rhGH in children with significant height deficit after kidney transplantation may produce a substantial increase in linear growth within the first year of therapy, but the magnitude of growth response may decline thereafter [55]. Calcimimetics may be considered in children with severe persistent hyperparathyroidism, although they may exacerbate low turnover bone disease, even in patients with high serum PTH levels [56].

Evaluation of Renal Bone Disease in Children

Although assessment of bone health is a key element in the clinical care of children with CKD, a paucity of high-quality evidence has led to wide variations in clinical practice in the diagnosis and management of pediatric CKD-MBD. In an effort to standardize care, the European CKD-MBD and dialysis working groups have recently proposed the following clinical practice guidelines for bone evaluation in children with CKD stages 2–5 [57]:

1. Clinical evaluation of height, growth velocity, blood pressure and a musculoskeletal examination, focusing on bone pain, deformities, and fractures, should be performed at baseline and routine intervals. Assessment should be more frequent during periods of rapid growth, such as infancy and adolescence [57]. Ca intake from diet, nutritional supplements, and P-binders should also be assessed at regular intervals (see ▶ Chap. 71, “Nutrition, Growth, and Development”).
2. Traditional biochemical markers of mineral metabolism, including Ca, P, PTH, 25-D, and alkaline phosphatase (ALP), should be measured at routine intervals. Other biomarkers should be measured for research purposes only.
3. Bone imaging, including bone densitometry (DXA or pQCT/HR-pQCT), bone biopsy, and cardiovascular evaluation (coronary artery computed tomography and ultrasound measures of carotid intima/media thickness and pulse wave velocity) are research tools that are not recommended in routine practice [57].

Biomarkers

No perfect biomarker exists for the assessment of all aspects of CKD-MBD; all currently available markers have limited sensitivity or specificity to predict intermediate endpoints like alterations in bone (mineralization and turnover) and vessels (vascular calcifications) or hard end points like fractures or cardiovascular mortality [58]. Thus, a thorough assessment of CKD-MBD parameters requires serial assessment of P, Ca, and PTH levels, all of which should be considered together during clinical decision making [59]. Normal ranges for serum P, Ca, and ALP are age-dependent; ALP values are also gender-specific (Table 1). Monitoring should be based on CKD stage, rate of CKD progression, severity of abnormalities, clinical signs and symptoms, and concomitant medications [57, 60, 61]. Due to the deleterious effects of acidosis on kidney function and on skeletal health, serum bicarbonate levels should also be monitored regularly and maintained within the normal range [57].

PTH directly stimulates osteoblast activity and circulating values of this hormone have been used

Table 1 Age-specific ranges for calcium, phosphate, and alkaline phosphatase

Age range	Calcium (mmol/L)	Ionized calcium (mmol/L)	Phosphate (mmol/L)	25-D (nmol/L)	ALP (IU/L) in boys	ALP (IU/L) in girls
Birth-5 months	2.18–2.83	1.22-1.40	1.50–2.40	75–120	91–476	91–476
6–12 months	2.18–2.75	1.20–1.40	1.50–2.40	75–120	131–476	131–476
1–5 years	2.35–2.70	1.22–1.32	1.50–2.10	75–120	151–342	151–342
6–12 years	2.35–2.58	1.15–1.32	1.20–1.90	75–120	137–424	137–424
13–20 years	2.20–2.55	1.12–1.30	0.70–1.50	75–120	124–474 from 13 to 15	66–262 from 13 to 15
					91-339 from 15 to 17	59-126 from 15 to 17
					64-158 above 17	54-96 above 17

For calcium, the conversion factor from mmol/L to mg/dL is to multiply by 4.0. The calculation formula for corrected calcium (CaC, mmol/L) using measured calcium (mmol/L) and albuminemia (g/L) is the following: $CaC = Ca - 0.25 \times (\text{albuminemia} - 40)$. If albuminemia is not available, CaC may be calculated with protidemia (g/L) with the following formula: $Cac = Ca/(0.55 + P/160)$. For phosphate, the conversion factor from mmol/L to mg/dL is to multiply by 3.1. PTH normal ranges are not presented here since they vary widely with the assay, we propose to reason in terms of x-UNL (x times the upper normal limit for the local assay)

for decades to predict bone turnover in children with all CKD stages [62]. Uncontrolled secondary hyperparathyroidism in CKD is characterized by sustained high PTH levels which contributes to an efflux of Ca and P from bone, together contributing to deleterious effects on the skeleton (osteitis fibrosa), heart, and vasculature (vascular calcifications) [63]. Unfortunately, PTH measurement by all assays is an imperfect predictor of bone turnover and ideal target ranges for PTH remain controversial in all CKD stages [64, 65]. Due to the skeletal PTH resistance that develops as CKD progresses [66], serum PTH levels above the normal range are required to maintain normal rates of bone formation in patients with severe CKD. Two different sets of recommendations related to target PTH levels in dialyzed children exist – the first from the Kidney Disease, Improving Global Outcomes (KDIGO) Working Group and the second from the European Pediatric Dialysis Working Group (EPDWG). Based on bone histology data from the 1990s, which documented more severe growth retardation in patients with PTH < 300 pg/ml along with data from a prospective randomized trial that compared the effects of P-binders and the intermittent administration of vitamin D analogs on the control of the skeletal lesions of secondary hyperparathyroidism, KDIGO guidelines suggest that PTH levels should be maintained between 2- and 9-times the upper limit of normal (i.e., 120–540 pg/mL) [30, 58, 67]. Subsequent to the development of the KDIGO guidelines, new data suggested that high bone turnover lesions can occur at lower PTH levels, particularly in children new to dialysis [68], and data obtained in the International Pediatric Peritoneal Dialysis Registry Network (IPPN) suggested that a range of PTH between 1.7 and 3 times the upper limit of normal (i.e., 100 and 180 pg/mL) was associated with optimal bone quality while higher PTH levels were associated with an increased frequency of bone pain, limb deformities, extraosseous calcifications, and radiographic evidence of osteomalacia or osteopenia [2, 58]. Thus, in 2006, the EPDWG Working Group suggested that PTH levels be maintained between 2- and 3-times the upper limit of normal (120–180 pg/mL) in dialyzed children.

Current data suggest that a combination of biomarkers may be helpful in the management of bone disease in pediatric CKD. In a cross-sectional cohort of 161 pediatric patients undergoing maintenance peritoneal dialysis, PTH levels below 400 pg/ml in combination with total ALP levels below 400 IU/L provided the highest correct prediction rate for patients with both normal bone turnover and normal mineralization [41]. In this study, levels of PTH were higher and serum Ca levels were lower in patients with defective mineralization, irrespective of bone turnover [41]. Thus PTH and alkaline phosphatase trajectories should together guide therapy which should also aim to keep Ca and P levels in the normal range.

In pre-dialysis CKD, data for defining optimal PTH targets are sparse. PTH, P, and FGF23 levels are known to increase well before CKD stage 5 [69]. Concomitantly, bone formation increases in CKD stages 3 and 4 [31]. Data obtained with bone imaging techniques favor strict control of PTH levels; not only do low cortical BMD Z-scores predict subsequent fractures [70] but cortical volumetric bone mineral density is significantly lower in patients with elevated PTH levels than in those with PTH within the normal range [71]. It is important to note that different PTH assays may yield discrepant results, and limited evidence exists that newer assays improve the assessment of bone turnover compared to older assays.

Bone Imaging

Evidence for routine radiological evaluation of bone disease in pediatric CKD is scarce [57]. Severe abnormalities in bone volume and/or mineralization may be observed on conventional radiographs; these films should thus be obtained in children with bone pain, those with suspected atraumatic fractures, and those with genetic diseases with specific bone involvement [72, 73]. Bone radiographs are also useful in patients with clinical manifestations suggestive of avascular necrosis, proximal femoral slipped epiphyses, or in the assessment of skeletal maturity [57]. Skeletal age can be determined on an X-ray of the left wrist and thus predicted adult height can be calculated using the automated Greulich-Pyle bone age determination system. In infants and young children, knee X-rays may be used to evaluate an active metaphyseal area [57]. Extraskeletal calcifications may also be visualized on plane films.

Dual X-ray absorptiometry (DXA), techniques derived from quantitative tomography (pQCT, HR-pQCT), magnetic resonance imaging (MRI), and ultrasound evaluation of bone quality are used in research protocols, but limited evidence exists that DXA (lumbar spine and whole-body) and pQCT results are congruent in pediatric CKD [74] and it remains unclear as to whether DXA scores predict fracture risk in the pediatric CKD population. A recent study showed that combination of routine biomarkers were better predictors of cortical BMD evaluated by pQCT, and BMD measurement by DXA did not correlate with biochemical data or pQCT measures [3]. Thus, these imaging techniques are not recommended for routine screening tools of bone health or fracture risk prediction in pediatric CKD patients [57].

Cardiovascular Disease in CKD

Cardiovascular disease (CVD) is a life-limiting comorbidity in patients with CKD and is rapidly progressive, especially in dialysis patients. The American Heart Association guidelines for cardiovascular risk reduction in high-risk pediatric patients [75] stratify pediatric CKD patients as “high risk” for the development of CVD, with associated “pathological and/or clinical evidence for manifest coronary disease before 30 years of age.”

Epidemiology of Cardiovascular Disease

Data from the USRDS database on over 23,000 children starting dialysis therapy in the United States between 1990 and 2010 demonstrate decreasing rates for overall and cardiovascular mortality in this population [76]. However, data from large registries worldwide report that between 18 and 21% of deaths in children on dialysis are from CV causes [77, 78]. CVD is the primary cause of death in 57% of children receiving HD, 43% of those treated with PD, and 30% of pediatric transplant recipients [79].

Risk Factors for CVD

In addition to traditional “Framingham” risk factors for CVD (i.e., hypertension, dyslipidemia, and smoking) found in the general population, uremia-related risk factors for vascular disease include hypercalcemia, hyperphosphatemia, high PTH, very low or high vitamin D levels, a multitude of middle and large molecular weight substances together labeled “uremic toxins,” anemia, chronic inflammation, oxidative stress, hyperhomocysteinemia, and malnutrition [80]. A number of potential iatrogenic or treatment-related risk factors such as exposure to a high Ca load from dialysate, Ca-based P-binders and vitamin D therapy, advanced glycation end-products, metabolic acidosis, and warfarin therapy can also contribute to the pro-calcific effect of the uremic milieu.

Assessment

“Hard end-points” such as cardiovascular events and death are infrequent in children; thus, surrogate endpoints including left ventricular mass index (LVMI), carotid artery intima-media thickness (cIMT), pulse wave velocity (PWV), and direct evidence of calcification in the coronary arteries and cardiac valves on multi-slice CT scan are used to identify and quantify the burden of cardiovascular disease in pediatric studies. Even small increments in measurements of these parameters are highly predictive of future cardiovascular events in the general population and in adults with CKD. In addition, numerous biomarkers of vascular damage and future cardiovascular events have been described and some validated against “hard end-points” in adult dialysis patients; these include FGF23 [81], the physiological calcification inhibitors (fetuin-A, matrix gla-protein and osteoprotegerin) [82], endothelial microparticles, and cardiac troponin levels [83].

Clinical Studies in Children

A prospective observational study of over 700 - European children with CKD, the Cardiovascular Comorbidity in Children with CKD (4C) study, showed that left ventricular hypertrophy (LVH) was present in 33%, cIMT was elevated in 42%, and PWV was increased in 20% [84]. Similar results were found in reports from the CKiD (Chronic Kidney Disease in Children) study [85].

Although most pediatric studies are small, often single-center, and cross-sectional, remarkably similar associations have been observed between risk factors and cardiovascular disease. A strong linear association has been noted between deteriorating vascular measures and time spent on dialysis [5, 6, 86–89]. Prolonged exposure to the uremic milieu with high, often worsening control of secondary hyperparathyroidism and hyperphosphatemia, exposure to pro-inflammatory agents such as advanced glycation end-products and oxidative stress, and reduced levels of the circulating calcification inhibitors all contribute toward deleterious structural and functional changes in the vasculature. Vascular measures consistently and significantly correlate with circulating Ca, P [86, 87, 89], and PTH levels [6, 86, 89], as well as medication dosages of Ca-based P-binders and vitamin D compounds, suggesting that dysregulated mineral metabolism is central to the vasculopathy of CKD. These modifiable risk factors thus require careful monitoring and strict control from the earliest stages of CKD since increases in cIMT and PWV begin even in the first decade of life in children on dialysis [89] and in those with pre-dialysis CKD [87, 89, 90]. As first demonstrated by Goodman and colleagues, calcifications progress rapidly in patients on dialysis with a doubling of the coronary artery calcification score on CT scan in patients with evidence of calcification on a baseline scan [5]. This suggests that in the pro-calcific and pro-inflammatory uremic milieu “Ca begets Ca” and that primary prevention of calcification, starting in the earliest stages of CKD, is of critical importance.

FGF23 has been linked to cardiovascular disease in patients with all stages of CKD and recent experimental data have defined a direct role for FGF23, independent of changes in mineral metabolism, on pathological changes in cardiac myocytes [91]. Although the effects of circulating FGF23 on mineral metabolism require the presence of Klotho, as the co-receptor of FGF receptors [92], some of the effects on the cardiovascular system appear to be Klotho-independent. FGF23 levels are often hundreds- to thousands-fold higher in patients with kidney disease as compared to individuals with normal kidney function and these values have been associated with an increased prevalence of left ventricular hypertrophy [93] and with premature mortality in adults with all stages of CKD [81]. Recent experimental data have demonstrated that these associations may reflect a direct effect of FGF23 on the myocardium that induces myocyte hypertrophy in a Klotho-independent manner [91]. However, despite the multiple associations between FGF23 and cardiovascular disease, FGF23 levels were not associated with arterial calcifications [94] in a recent large study in patients with CKD stages 2–4.

Pathophysiology of Vascular Calcification

Vascular calcification is an active, highly regulated process and not merely a passive deposition of Ca and P in dead or dying cells [95]. Ca deposition is observed primarily in intimal atherosclerotic plaques in individuals with preserved kidney function, while hydroxyapatite crystals occurs primarily in the tunica media in the context of CKD [96] (Fig. 4). Vascular smooth muscle cells (VSMCs) in the tunica media undergo specific phenotypic changes in the presence of hypercalcemia and hyperphosphatemia; these changes include cellular apoptosis, osteo/chondrocytic differentiation, and the release of small membrane-bound bodies (vesicles) that form a nidus for the deposition of hydroxyapatite [7, 95]. VSMC transformation to an osteo/chondrocytic phenotype is characterized by the upregulation of bone-specific transcription factors and matrix proteins, including RUNX2/CBFA1, osterix, and ALP, that in turn lead to accelerated calcification. Indeed, osteoblasts and VSMCs have a common mesenchymal origin and, in patients with CKD, RUNX2 triggers mesenchymal cell to osteoblast transformation [95, 97].

Elevated serum P concentrations are a key factor triggering osteoblastic differentiation of VSMCs [95], likely mediated in part by expression of the sodium-dependent P transporters PIT-1 and PIT-2 [96]. Upregulation of pro-mineralization factors such as osteopontin, bone sialoprotein, osteonectin, ALP, type I collagen, and bone morphogenic protein-2 (BMP-2) is also potentiated by the uremic milieu [89, 98], while expression of calcification inhibitors, such as fetuin A and matrix gla protein, is suppressed [99]. Alterations in the *WNT* signaling pathway may also play a critical role in the development of vascular calcification [100]. The importance of circulating inhibitors of the calcification process was recently confirmed by several studies using a novel in vitro test (T50 test) to determine the calcification propensity in blood; this quantifies the calcification inhibition of serum that results in the formation of (mainly fetuin-containing) primary calciprotein particles [101].

CKD-MBD Management

Goals of Treatment:

Historically, treatment of CKD-MBD focused on the management of renal osteodystrophy and secondary hyperparathyroidism. More recently, recognizing that serum Ca, P, and PTH levels and vascular calcification are associated with mortality and premature cardiovascular events, treatment goals have focused on preventing premature death and cardiovascular complications. In addition, the high Ca requirement of the growing skeleton must be recognized and appropriately managed to prevent fractures and debilitating bone disease. Principles of management include: maintaining Ca, P, PTH, ALP, and 25D levels within age- and CKD-specific ranges, following trends (rather than single values) of these markers; correcting metabolic abnormalities such as acidosis and malnutrition; promoting optimal growth; and avoiding extraskeletal calcifications. A key objective of CKD-MBD management should focus on primary prevention. Treatments that correct abnormal concentrations of Ca, P, PTH, and vitamin D have demonstrated efficacy across many randomized trials, but high-grade evidence that these therapies affect clinical outcomes such as fractures and cardiovascular

Fig. 4 Model showing the phenotypic changes in vascular smooth muscle cells (VSMCs) in response to mineral dysregulation and uremic insults. In response to injury, VSMCs undergo osteo-chondrocytic changes and convert to bone like cells (osteoblasts). In addition, VSMCs release vesicles that transport the intracellular calcium out of the cell and deposit it in the extracellular matrix, thereby preventing cell death. Extracellular matrix calcification is clinically seen as an increased carotid intima-media thickness (cIMT) and leads to vessel stiffness (increased pulse wave velocity (PWV) and reduced distensibility

events is lacking in children. Extrapolation of findings from studies in adults with CKD may not be appropriate as the growing skeleton of children needs Ca [102], with devastating consequences into adult life if normal bone mineralization has not taken place before peak bone mass is reached [4].

In recent years international guidelines from Kidney Disease Improving Global Outcomes (KDIGO) [30], the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (K/DOQI) [103], and the European Society of Pediatric Nephrology (ESPN) [55, 61, 104] as well as many national guidelines such as from the National Institute of Health and Care Excellence (NICE) [105] in the UK have included the management of CKD-MBD in children, and produced clinical practice recommendations on several aspects of CKD-MBD management. As evidence of "hard end-points" is lacking in children, many recommendations are "weak statements" or are opinion based only and must be carefully considered and adapted to individual patient needs based on the clinical judgment of the treating physician.

Dietary Management of CKD-MBD

Regular dietary counseling is an essential part of CKD-MBD management and is discussed in detail in ▶ Chap. 71, “Nutrition, Growth, and Development.” As high FGF23 levels are observed before abnormalities in serum Ca, P, or PTH develop, optimal control of serum P concentration is a crucial element of preventative management. K/DOQI [103] and the Pediatric Renal Nutrition Taskforce [106], have published guidelines on the dietary management of Ca and P in children with CKD2-5D. Both groups recommend regular dietary counseling from early CKD, limiting dietary P intake to within the age-appropriate normal ranges for children in the mild-moderate stages of CKD and to the lower limit of the normal range (K/DOQI suggests 80% of dietary recommended intake) in patients with advanced CKD who have persistent hyperphosphatemia or hyperparathyroidism [106, 107].

The average P intake of both adults and children on a “western diet” is approximately 1500–2000 mg/day, and 60–70% of the dietary intake is absorbed. Importantly, processed foods are likely to contain inorganic P additives (such as phosphoric acid and sodium phosphate), which are almost completely absorbed, unlike organic phosphates that have a lower bioavailability. Additives may increase food P content by 60–70 mg per 100 g of product [108]. Processed foods with significant amounts of added inorganic P include meat, dairy and bakery products, and drinks such as colas; their presence but not their quantity is indicated as an “E number.” In addition, inorganic phosphates are added to several medications, such as antacids and many anti-hypertensive medications as an excipient, and can significantly increase the daily P intake.

Of note, aggressive dietary P restriction is difficult since it may compromise adequate intake of other nutrients, especially protein and Ca [109]. P intake is directly linked to protein intake, with 10–12 mg of P accompanying each gram of protein; any reduction in P intake should not compromise protein intake. In a recent study 67% of children with CKD stages 4–5 had a dietary Ca intake below the recommended nutrient intake, and additional Ca from medications, mainly in the form of P binders, was required to maintain nutritional Ca requirements [109].

Phosphate Binders

As renal function deteriorates, dietary P control becomes more difficult and overt hyperphosphatemia often develops. Phosphate binders (P-binders) reduce intestinal P absorption by forming poorly soluble complexes with P in the intestinal tract; these binders are of two main types: Ca-based and Ca-free (Table 2). It remains uncertain when along the spectrum of CKD P-binders should be initiated, what level of serum P should be targeted to improve outcomes, and whether all P-binders are equivalent in terms of long-term outcomes. No evidence exists that specific target levels of serum P improve clinical endpoints. In a randomized clinical trial in adults with an eGFR of 20–45 ml/min/1.73 m^2, increases in coronary calcification were noted in patients with normal serum P levels who were treated with Ca, lanthanum, and/or sevelamer binder therapy, but not in placebo treated patients [110]. Similar data are not available for children.

Ca-Based P-binders

KDOQI recommendations for the treatment of children with CKD stages 2–5 suggest that the choice of P-binders therapy should be guided by serum Ca levels [111]. Ca-based P-binders should be used as first-line therapy except in those with overt hypercalcemia [105]. Several Ca salts, including Ca carbonate, Ca acetate, and Ca citrate, are commercially available. Ca carbonate is the most commonly used compound, and studies in adults and children have shown its efficacy in controlling serum P concentrations [63, 68, 112]. Ca acetate contains 25% of elemental Ca (in contrast to Ca carbonate which contains 40%) and is a more effective binder per unit Ca content than is Ca carbonate (Table 2). Ca citrate and ketoglutarate are also effective P-binders, but gastrointestinal side effects and high cost limit their use. Due to the stimulatory effects of Ca on

Table 2 Phosphate binders

Compound	Formulation(s) available	Calcium Content (%)	Calcium Absorbed (%)	Phosphate Bound per mg Ca^{++} Absorbed	Comments
Calcium carbonate	250 mg, 500 mg, 1.25 g, 2.5 g tablets or as 250 mg/5 ml liquid	40	20–30	≈ 1 mg/ 8 mg	High Ca load, cheap, few GI side effects
Calcium acetate	475 mg or 950 mg tablets	25	22	≈ 1 mg/ 3 mg	Less Ca load than $CaCO_{3,}$ inexpensive, GI side effects more common particularly in infants
Sevelamer hydrochloride or sevelamer carbonate	800 mg tablets for both or 2400 mg sachet (for sevelamer carbonate only)	0	0	NA	Ca^{++} and Al^{+++} free, acts as cholesterol-binding resin and lowers serum cholesterol, binds fat soluble vitamins, expensive, difficult to administer to younger children, metabolic acidosis (with hydrochloride preparation)
Aluminum containing binders	100 mg capsules	0	0	NA	Very effective P-binding but risk of aluminum toxicity; can be used short term under close monitoring of aluminum levels; recommended for "rescue therapy" from severe hyperphosphatemia only
Mg + Ca carbonate	Variable strength tablets	Variable	20–30% of Ca	≈ 1 mg/ 2.3 mg	Less Ca^{++} load, GI side effects, long-term effects?
Lanthanum carbonate	Chewable tablets or sachets with 500 mg, 750 mg, or 1000 mg	0	0	NA	Poorly tolerated as gastrointestinal side effects are very common; accumulates in bone and long-term effects in the growing bone are unknown; expensive
Sucro-ferric oxyhydrixyde	500 mg chewable tablets	0	0	NA	Gastrointestinal side effects – diarrhea, nausea

NA not applicable

FGF23 expression [113], Ca-based P-binders appear to be less effective in lowering FGF23 levels than do non-Ca binders such as lanthanum and sevelamer [114–116]. Table 3 provides practical tips on the use of P-binders and vitamin D medications.

Ca-Free P-binders

Large doses of Ca carbonate may lead to hypercalcemia, particularly in patients treated with vitamin D or those with adynamic bone disease [63] and adult pre-dialysis CKD patients have been shown to be in a positive Ca balance when receiving as little as 1500 mg/day of Ca carbonate [117]. Current KDIGO recommendations do not specify maximum doses of Ca-based binders, but acknowledge the potential existence of a safe upper limit of Ca dose [111]. While the growing skeleton has a higher demand for Ca, Ca-free P-binders are indicated in patients with hypercalcemia, either alone or in combination with Ca-based binders. Table 2 lists the commonly used non-Ca-based binders, their P-binding capability, and their side effects.

– ***Sevelamer Hydrochloride***, a Ca- and aluminum-free hydrogel of cross-linked polyallylamine, lowers serum P without inducing hypercalcemia in adult patients treated with hemodialysis [118]. Because hydrochloric

Table 3 Practical tips on the use of phosphate binders and vitamin D medications

Phosphate Binders	Vitamin D
Children and their caregivers benefit from regular diet education sessions with help from renal dietitians, as well as doctors and nurses, to understand the complexities of their renal diet	Serum concentrations of 25D are the best marker of the vitamin D status of an individual
	Frequency of measurement of 25D levels should not be more than 3-monthly
	$1{,}25(OH)_2D$ should not be measured for routine assessment of vitamin D status
Should be given with meals and high P snacks, never on an empty stomach	Ergocalciferol or cholecalciferol may be used interchangeably if daily, weekly, or monthly treatment regimens are used
Significantly more Ca is absorbed when Ca containing P-binders are not given with meals	
Do not give a fixed dose, but adjust the dose depending on the P content of the meal or snack	All vitamin D analogs are adsorbed to plastic tubing to varying degrees, and therefore should not be given via feeding tubes
Calcium carbonate requires an acidic pH in the stomach to dissociate and bind P. Hence, calcium carbonate must not be given along with an antacid or H2-antagonist or sodium bicarbonate	Vitamin D analogs increases intestinal P absorption from around 60–90%; calcitriol use may be limited by worsening hyperphosphatemia and hypercalcemia
Calcium will precipitate in the duodenum as calcium carbonate if given with sodium bicarbonate medications	A vitamin D treatment regimen guided by age and baseline vitamin D concentration is recommended
Restriction of dairy foods as part of a P controlled diet limits Ca intake. Additional Ca from medications is required to meet the KDOQI guideline of 100–200% normal recommended Ca intake	An intensive replacement phase (usually for 3 months) followed by a maintenance phase is recommended by most guidelines

acid is released when P binds, this medication may induce a metabolic acidosis. The use of sevelamer carbonate circumvents this side effect [119]. Two randomized controlled studies in children have demonstrated that sevelamer hydrochloride has an equivalent P-binding capacity as Ca acetate, and does not increase serum Ca levels [120, 121]. In addition to its effects on serum P concentrations, sevelamer decreases concentrations of total serum cholesterol, decreases low-density lipoprotein cholesterol, and increases high-density lipoprotein levels [122].

- ***Aluminum Hydroxide*** is a very efficient P-binder, but its long-term treatment can lead to adynamic bone disease, encephalopathy, and anemia [123], hence aluminum may only be used as a short-term "rescue" treatment when severe hyperphosphatemia is present associated with hypercalcemia that is not responsive to other P-binders [63, 112]. If this drug is used, regular monitoring of aluminum blood levels is essential.
- ***Lanthanum Carbonate*** binds intestinal P more effectively than Ca carbonate and sevelamer. However, patients on extended treatment show increased lanthanum serum levels. Lanthanum also accumulates in the bone in dialysis patients, where its presence persists despite discontinuation for as long as 2 years [124]. In light of the experience with aluminum toxicity, lanthanum containing P-binders are currently not recommended in children with CKD. Additional long-term studies are needed to confirm the absence of toxicity before this agent is recommended for widespread use.
- ***Iron-Based P-Binders*** reduce serum P and FGF23 concentrations while simultaneously increasing serum iron parameters [125, 126]. A recent randomized open-label study has shown that sucroferric oxyhydroxyde is as effective as Ca acetate in controlling serum P levels in children with CKD [126]. Similar to other P-binders, adverse events are primarily GI-related.
- ***Magnesium Salts*** have a relatively weak intestinal P-binding activity. Diarrhea, hyperkalemia, and hypermagnesemia are their main side effects and the long-term effects of an increased magnesium load are not clear.

Magnesium-free dialysate solutions should be used in patients treated with maintenance dialysis.

- ***Newer P-Binders***: Intestinal P absorption is regulated by sodium-dependent P co-transporter type 2b (NPT2b), therefore treatment with niacin (vitamin B3) or its metabolite nicotinamide/niacinamide, both of which modulate NPT2b expression, result in a sustained reduction in serum P concentrations in adult dialysis patients [127]. However, in a randomized trial of adult HD patients, NPT2b inhibition was not effective in reducing serum P concentrations [128]. Targeting salivary P using P-binding chewing gum has also been proposed [129]. These agents have not been studied in children.

Vitamin D Treatment

The K/DOQI [103], recent KDIGO update [111] and the ESPN [61, 130] have all developed guidelines on the management of vitamin D deficiency and use of active vitamin D analogs in children with CKD stages 2–5. Native vitamin D therapy is indicated in children with pre-dialysis CKD and those treated with maintenance dialysis who have evidence of vitamin D deficiency or insufficiency while active vitamin D therapy is indicated for the treatment of secondary hyperparathyroidism despite normal 25D levels, provided there is no hypercalcemia and/or hyperphosphatemia. Table 3 provides practical tips on the use of vitamin D medications.

Native (Nutritional) Vitamin D Supplementation

All guidelines suggest that serum 25D levels are routinely measured in CKD patients [61], although target ranges vary between guidelines. The ESPN guidelines suggest that serum 25D levels be maintained above 75 nmol/L (30 ng/ml), and below 120 nmol/L (48 ng/ml) [61]. These levels maintain optimal gut Ca absorption and prevent seasonal fluctuations that can predispose even healthy children to nutritional rickets [131]. In the only RCT of 25D therapy in children with CKD stages 2–4, children on ergocalciferol who achieved 25D levels >75 nMol/L had a significantly longer time to development of secondary hyperparathyroidism compared to those on placebo [10]. No clear consensus exists between guidelines on the type of native vitamin D supplement (ergo vs cholecalciferol), its dosage, frequency of administration, or duration of treatment in healthy children or children with CKD [131]. All guidelines recommend a loading regimen or intensive replacement period for a variable duration of 4–12 weeks followed by a maintenance regimen [61, 103]. K/DOQI and the ESPN guidelines recommend escalating doses for intensive replacement depending on the baseline 25D level [61, 103]; cholecalciferol doses range 2000–8000 IU/day for intensive phase replacement and 1000–2000 IU/day for maintenance therapy. Fortunately, vitamin D has a wide therapeutic window and hypercalcemia, hypercalciuria, and symptomatic toxicity has been reported only when serum 25D levels exceed 250 nmol/L.

Active Vitamin D Sterols

Treatment with active vitamin D sterols is indicated in pediatric CKD patients whose serum PTH levels remain elevated despite normal serum 25D and P levels. Alfacalcidol (1-α hydroxyvitamin D_2) or calcitriol (1,25-dihydroxyvitamin D_3) are most commonly used. An initial dose of 5–10 ng/kg/day is effective and safe in most children with CKD; the lowest dose that maintains normal serum PTH levels should be used.

With prolonged treatment with vitamin D analogs, children may develop adynamic bone disease, which has been associated with a reduced growth rate and frequent episodes of hypercalcemia [132]. Calcitriol usage may contribute to extraosseous calcifications in children with ESKD [5–7, 133]. Synthetic vitamin D analogs have been developed to reduce intestinal Ca and P absorption at equipotent PTH suppressive action. Three sterols have been approved – 22-oxacalcitriol (maxacalcitol) in Japan and 19-nor-1,25-$(OH)_2D_2$ (paricalcitol) and 1 α-(OH) D_2 (doxercalciferol) in the United States. A comparative trial of calcitriol and doxercalciferol in pediatric dialysis patients revealed no differences in the control of secondary hyperparathyroidism, development of hypercalcemia, or increase in FGF23 levels [38]. Although both agents suppressed bone turnover, neither were able to normalize histomorphometric parameters of skeletal mineralization and a mineralization defect remained in the majority of patients. Two randomized trials have demonstrated that vitamin D analogs do not improve cardiac function for patients with CKD stages 3–5 during 1 year of treatment [134, 135].

All activated vitamin D analogs increase FGF23 secretion. Although the consequences of these increased FGF23 levels in dialyzed patients remain to be completely determined, current evidence suggests that excessive circulating FGF23 is associated with increased mortality rates and cardiovascular disease [81]; however, prospective randomized trials are required.

Calcimimetic Agents

Cinacalcet is an allosteric modulator of the Ca-sensing receptor (CaSR), which is expressed in several tissues, including the parathyroid glands. Cinacalcet enhances the CaSR sensitivity for extracellular Ca, reducing serum PTH, Ca, and P concentration for improved control of secondary hyperparathyroidism [136]. The largest RCT evaluating calcimimetic use, the Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events (EVOLVE) trial included 3883 adult patients on HD with baseline PTH levels of ≥300 pg/ml (31.8 pmol/l) and Ca concentration ≥8.4 mg/dl (2.1 mmol/l) [137]. Patients receiving cinacalcet were less likely to reach the primary composite end-point of time to death, myocardial infarction or hospitalization for a cardiovascular event (hazard ratio 0.88 (95 CI: 0.79-0.97)) [137]. Secondary analyses suggested benefit from cinacalcet for non-atherosclerotic cardiovascular events (like admission for heart failure) and a lower incidence of parathyroidectomy. A meta-analysis that included 23 RCTs with a total of 8481 adult dialysis patients failed to demonstrate a significant reduction in the risk of fractures, cardiovascular events, or mortality with cinacalcet treatment, despite a significant decrease in PTH and decreased incidence of parathyroidectomy [138].

Five industry-sponsored RCTs or open label trials have evaluated cinacalcet use in children on dialysis; of these, only two are published [139, 140]. Enrolled patients had baseline intact PTH levels above 300 pg/ml (6-fold upper limit of normal [ULN]) and Ca levels above 2.2 mmol/l; the primary end-point of at least a 30%-reduction in PTH from baseline was achieved in one study [139]. Five other prospective studies have reported that cinacalcet is effective in reducing PTH levels in children with baseline PTH values of 300–500 pg/ml (9-fold ULN), but report varying rates of hypocalcemic episodes after cinacalcet exposure.

A recent ESPN consensus statement [104] recommends the use of cinacalcet in dialyzed children older than 3 years of age who have persistent and severe hyperparathyroidism in the presence of high or high-normal Ca levels, despite optimized conventional management (including vitamin D sterols). Importantly, because cinacalcet can induce hypocalcemia, leading to potentially fatal arrhythmias or seizures, cinacalcet should not be started in patients with albumin-corrected Ca levels below 2.40 mmol/L. Cinacalcet must be carefully titrated against serum Ca and PTH, using the minimal effective cinacalcet dose used to maintain PTH levels in the desired target range. A fatal adverse event was reported in an adolescent girl with prolonged QT treated with cinacalcet [139]; thus, cinacalcet should not be started in patients with a prolonged QT interval and should be used with caution in patients with a history of seizures, cardiac arrhythmia, significant liver disease, and in those on medications that may increase the QTc or interfere with cinacalcet metabolism. Regular monitoring of serum Ca (ionized Ca, if available) and PTH levels is essential and conventional therapy, including nutritional Ca intake, Ca-based P-binders, vitamin D analogs, and dialysate Ca, may need to be adjusted to achieve normal circulating Ca, P, and PTH concentrations.

A newer calcimimetic, etelcalcetide, is a synthetic peptide that allosterically activates the CaSR in the extracellular domain of the receptor, located on the parathyroid chief cells. By binding to the CaSR, etelcalcitide enhances the activation of the receptor by extracellular Ca, which results in decreased PTH secretion [141]. This mechanism contrasts with cinacalcet, which directly lowers PTH by increasing the sensitivity of the CaSR to extracellular Ca [136]. Etelcalcitide is administered intravenously after each HD session, potentially improving patient compliance. Studies in adults suggest that etelcalcetide decreases serum PTH levels to a similar extent as cinacalcet [142]; studies in children are ongoing.

Surgical Parathyroidectomy

With the availability of calcimimetics, the incidence of unremitting hyperparathyroidism and the need of parathyroidectomy has decreased [143]. However, in patients with contraindications or incomplete responses to calcimimetics, parathyroidectomy is still indicated in the context of persistent and recurrent hypercalcemia and hyperphosphatemia despite optimized medical management, progressive and debilitating bone disease, progressive extraosseous calcifications, and/or calciphylaxis [144]. Of note, other causes of hypercalcemia and bone disease must be excluded and parathyroid gland imaging by ultrasound or radionuclide studies should be used to identify the presence of parathyroid hyperplasia, hypertrophy, or adenomas that render a poor response to medical therapy. To avoid profound and life-long risk of hypocalcemia, autotransplantation of parathyroid tissue fragments in the abdominal subcutaneous layer may be an alternative to a total parathyroidectomy; the autotransplanted parathyroid tissues tend to grow and secret PTH.

Antiresorptive Therapies

Bisphosphonates and receptor activator of nuclear factor-κB ligand (RANKL) inhibitors (denusomab) are widely used for the treatment and/or prevention of osteoporosis and its complications in the general population. Bisphosphonates are eliminated via renal excretion and may cause an acute kidney injury that is not always fully reversible; their use even in adults with CKD is limited [145]. In pediatric CKD patients, the efficacy and safety of bisphosphonates have not been studied and only case reports of bisphosphonate use, mainly in the context of treating hypercalcemia or after renal transplantation have been reported [146]. Careful morphological assessment of bone structure and formation is required as bisphosphonates, via a deceleration of bone turnover, have the potential not only to aggravate preexisting adynamic bone disease, but also to impair longitudinal growth [147].

Denusomab is a human monoclonal antibody that binds and inhibits the actions of receptor activator of nuclear factor-κB ligand (RANKL), which is expressed by osteoblastic cells and mediates osteclastic bone resorption. Denusomab increases BMD and prevents fracture [148] in older women with low bone density. Preliminary studies indicate that the pharmacokinetics of denusomab is not affected by kidney function [148]. Its effectiveness has not been studied in children with CKD, and, of note, the risk of symptomatic hypocalcemia in children may be even more significant than in adults.

Growth Hormone Therapy

A recent guideline from the ESPN recommends that children in CKD stages 3–5 should be candidates for growth hormone therapy if they have persistent growth failure after other potentially treatable risk factors for growth failure have been adequately addressed, and provided they have growth potential [55]. Growth hormone therapy is discussed further in ▶ Chap. 71, “Nutrition, Growth, and Development.”

Dialysis

Standard prescriptions of peritoneal dialysis and hemodialysis remove insufficient amounts of P; 300–400 mg/day are removed daily with peritoneal dialysis and 800 mg in a standard hemodialysis session. By contrast, the use of daily, slow, continuous hemodialysis achieves excellent P removal, often allowing P-binders to be discontinued.

Indeed, some patients have developed hypophosphatemia and have required the addition of P to the dialysate solution to prevent the long-term consequences of hypophosphatemia [149, 150]. In the Frequent Hemodialysis Network (FHN) Daily Trial, dialysis six times per week lowered serum P by 0.18 mmol/l compared with dialysis three times per week [151]. Similarly, frequent nocturnal hemodialysis lowered serum P levels by 0.45 mmol/l compared with conventional hemodialysis. Higher dialysate Ca levels (1.5–1.75 mMol/L) are required in children on long daily or nocturnal HD; this is discussed in the chapter on hemodialysis (see Chapter 77).

Abstract

Anemia is common in children with chronic kidney disease (CKD), and the prevalence of this comorbidity increases with advancing CKD stage, affecting nearly all children treated with chronic dialysis. The primary causes of anemia in CKD are erythropoietin (EPO) deficiency/dysregulation, and iron deficiency/disorders of iron metabolism. This chapter reviews the pathogenesis of anemia and current approaches to clinical management including the initial diagnostic evaluation and the use of erythropoiesis stimulating agents (ESA) and iron supplementation. Clinical practice guidelines for anemia treatment goals are reviewed. Particular attention is paid to emerging novel anemia therapies made possible by our improved understanding of the molecular regulation of both EPO production and iron metabolism in the setting of CKD; longer-acting ESA, hypoxia inducible factor stabilizers/prolyl hydroxylase inhibitors, and novel approaches to iron supplementation and management of hepcidin-mediated iron restriction. The approach to ESA-resistant anemia is also discussed. Finally, the approach to prevention, evaluation, and management of anemia after successful kidney transplantation is discussed.

Introduction

The association between renal failure and anemia was first noted nearly two centuries ago, when the failure of erythropoiesis was described as “close to hemorrhage for impoverishing the red particles of the blood” [1]. The prevalence of anemia increases with advancing chronic kidney disease (CKD) stage, and affects nearly all children treated with chronic dialysis. Data from the Chronic Kidney Disease in Children (CKiD) cohort study have shown that median hemoglobin levels decline as the measured glomerular filtration rate (GFR) decreases below a level of 43 ml/min/1.73m^2 [2]. The emergence of recombinant human erythropoietin (rHuEPO) therapy more than 30 years ago revolutionized anemia management in patients with kidney disease and eliminated dependence on red blood cell transfusions for most patients. To date, erythropoiesis stimulating agents (ESA) and iron supplementation have been the standard of care to treat the anemia of CKD. However, anemia management remains challenging and treatment resistance is not uncommon. An improved understanding of the molecular regulation of both EPO production and iron metabolism has opened the door for the development of novel renal anemia therapies. This chapter reviews current approaches to the clinical management of the anemia of CKD, with focus on the mitigation of the primary causes of the anemia of CKD; EPO deficiency and dysregulation; and disorders of iron metabolism.

Pathogenesis of Anemia in CKD

Normal Erythropoiesis

Normal erythropoiesis becomes disordered in CKD. Erythrocytes lost to senescence and bleeding must be continually replaced. Erythropoiesis consists of the generation of mature red cells from multipotential myeloid stem cells and includes two distinct phases; an initial EPO-dependent phase which includes the proliferation and maturation of erythroid precursors, and a second phase of differentiation from erythroblasts to reticulocytes which is strongly iron-dependent [3, 4]. (Fig. 1) The glycoprotein hormone EPO is the 30.4-kDa product of the *EPO* gene on chromosome 7 [5, 6]. Prenatally, the liver is the primary site of EPO production, but this shifts to the kidney after birth, with a small additional amount continually produced by the liver [5]. EPO is produced by the interstitial fibroblast-like cells in the peritubular capillary bed of the renal cortex [5]. When injured, these cells transdifferentiate into myofibroblasts which synthesize collagen, losing the ability to produce EPO [5].

Hypoxia Stimulates Red Blood Cell Production

The cellular sensing of tissue hypoxia is the key signal leading to upregulation of EPO production, via EPO gene transcription through the actions of hypoxia inducible factor (HIF). The HIFs are transcription regulators which control the rate of gene transcription by binding to specific DNA sequences, and thus are key mediators of cellular adaptation to oxygen deprivation [4]. HIF comprises an oxygen sensitive α-subunit (HIF-1α, HIF-2α, or HIF-3α) and a stable β-subunit, and activates the transcription of genes containing hypoxia response elements, including the *EPO* gene

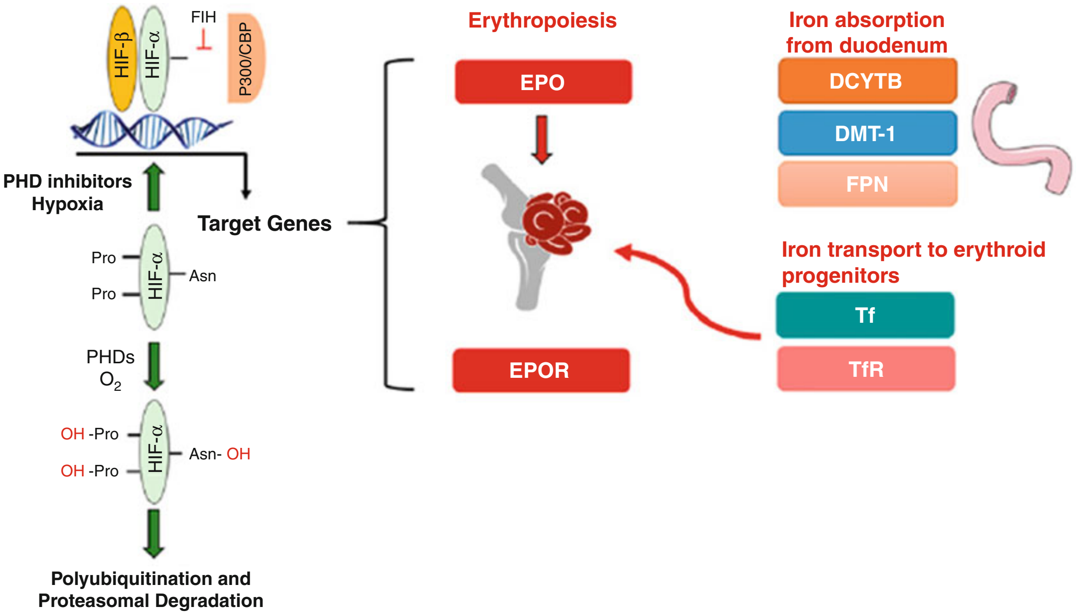

Fig. 2 Role of hypoxia-inducible factor α (HIF-α) in regulation of erythropoiesis [4]. (Reprinted with permission). Hypoxia signaling controls erythropoiesis by coordinating EPO synthesis with the expression of genes involved in iron metabolism. Under well-oxygenated conditions, the three oxygen-labile HIF-*α* subunits (HIF-1*α*, HIF-2*α*, and HIF-3*α*) are hydroxylated at specific proline (Pro) residues by PHD engines. Prolyl hydroxylation targets HIF-*α* proteins for ubiquitination by the von Hippel-Lindau (pVHL)-E3-ubiquitin ligase complex with subsequent proteasomal degradation. Under conditions of reduced PHD activity (e.g., hypoxia or pharmacologic inhibition), HIF-*α* escapes hydroxylation and translocates to the nucleus, where it forms a heterodimer with the constitutively expressed HIF-*β* subunit. The effective HIF-*α*/HIF-*β* complex activates the transcription genes whose promoters contain hypoxia response elements. The HIF-mediated activation of transcription requires the recruitment of coactivators such as p300/CREB-binding protein. An additional layer of regulation is due to factor-inhibiting HIF (FIH), which hydroxylates a specific asparagine (Asn) residue abrogating transcriptional cofactor recruitment. HIF-*α* stabilization results in the activation of genes in diverse biologic processes. For instance, HIF-2*α* induces EPO production from renal peritubular fibroblasts and hepatocytes, promoting erythroid progenitors' cell viability, proliferation, and differentiation through EPO receptor (EPOR) signaling. Genes expressed in duodenum, *duodenal cytochrome b reductase (DCYTB)* and *divalent metal transporter-1 (DMT1)*, along with *ferroportin* (*FPN*) are activated by HIF-2, increasing iron uptake while HIF signaling also controls the expression of iron transport genes *transferrin* (*Tf*) and *transferrin receptor* (*TfR*). O_2 oxygen; OH, hydroxide

[4, 7]. HIF-α proteins are continually produced, but in the presence of normoxia are "marked" (hydroxylated) for degradation by the HIF-prolyl hydroxylases [1]. (Fig. 2) Once hydroxylated at proline residues, HIF-α is targeted for ubiquitination and proteasomal degradation by the von Hippel-Lindau protein [1, 4]. Under hypoxic conditions, HIF-α is stabilized and, after nuclear translocation, dimerizes with the HIF-β subunit forming heterodimers that activate the *EPO* gene and other genes associated with iron metabolism [1, 4]. (Fig. 2) Notably, HIF-2α induces EPO production from both renal peritubular fibroblasts and from hepatocytes [4]. HIF-prolyl hydroxylase inhibitors have emerged as a promising class of therapeutic agents for the treatment of the anemia of CKD, as will be discussed later in this chapter.

Dysregulated Erythropoiesis in CKD

Decreased EPO production by injured fibroblast-like epithelial cells is not the only means by which endogenous EPO production is decreased in kidney disease. Diminished oxygen consumption by diseased renal tissue leads to dysregulation of EPO production by increasing tissue oxygen pressure, which in turn leads to decreased HIF stability

[8]. The result is decreased EPO transcription occurring independently of damage to EPO-producing cells.

Iron Is Required for the Synthesis of Hemoglobin

Effective erythropoiesis depends not only on erythropoietin production, but also on the availability of iron, and incorporation of iron into erythroblasts is a rate-limiting step in the maturation of red blood cells in the bone marrow. Because iron does not have an excretion regulation pathway, dietary intake, intestinal absorption, and iron recycling must be finely regulated at multiple stages of the red blood cell life cycle [3, 4]. (Fig. 3) The majority of this iron is supplied by macrophages which recycle iron from senescent red blood cells, while only 1–2 mg per day of iron comes from intestinal absorption [3]. Transferrin is the glycoprotein iron transporter that binds tightly but reversibly to iron in plasma, preventing the oxidative stress that freely circulating iron would induce. Iron that has been transported into the circulation bound to transferrin is released to erythroblasts via the interaction of transferrin with the transferrin receptor and receptor-mediated endocytosis [3].

Hepcidin Regulates the Ferroportin-Based Movement of Iron

The iron-regulatory protein hepcidin has emerged as the key regulator of iron homeostasis [9]. Hepcidin is produced in hepatocytes and regulates both intestinal iron absorption and body

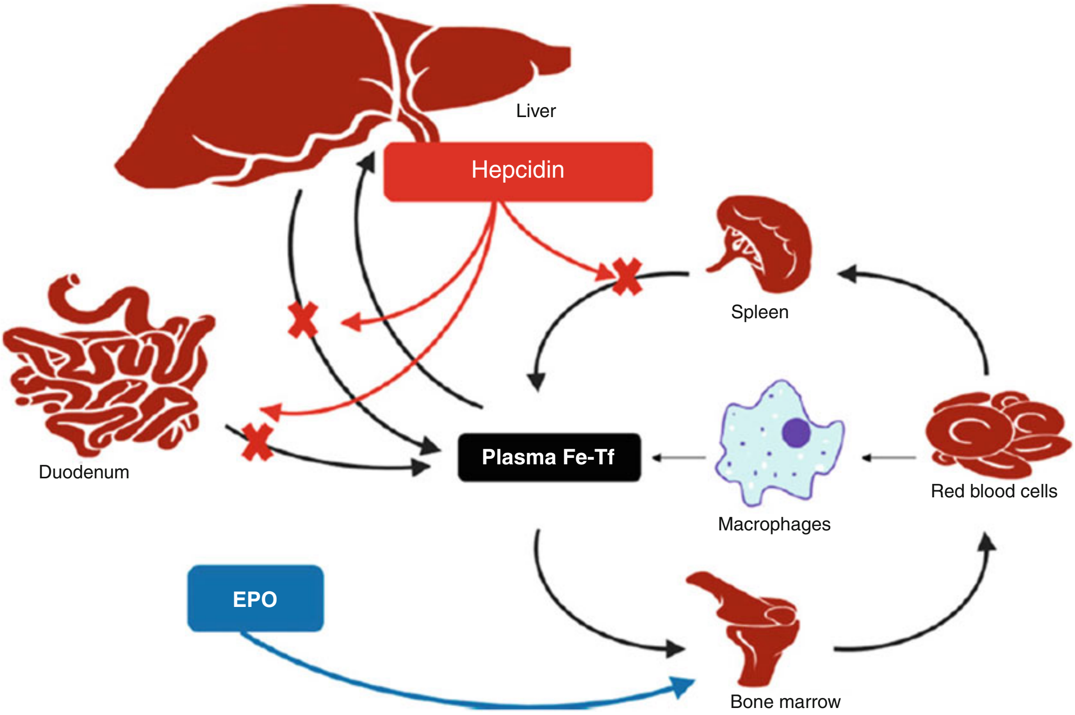

Fig. 3 Iron metabolism is a tightly controlled process [4]. (Reprinted with permission). Iron metabolism is a tightly regulated process. Iron is absorbed in the gut and bound to soluble transferrin. Iron is then moved to storage in the bone marrow and used for erythropoiesis. Additional stores are repleted by macrophage uptake of iron from RBC destruction. EPO induces RBC production, leading to the mobilization of iron stores from the bone marrow. Hepcidin, which is produced by the liver and often stimulated by inflammation, leads to decreased iron uptake from the gut and decreased mobilization of iron stores. Fe-Tf, iron-bound transferrin

iron distribution through its post-translational suppression of cell membrane expression of ferroportin, which is the sole cellular iron exporter. Hepcidin binding to ferroportin causes internalization and lysosomal degradation of ferroportin, which results in downregulation of dietary iron absorption via intestinal enterocytes, and inhibits the release of stored iron from reticuloendothelial cells [10]. In this way, hepcidin prevents the utilization of absorbed or stored iron for erythropoiesis by the bone marrow. Hepcidin expression is induced by inflammation in general and in particular by the inflammatory cytokine IL-6. Hepcidin is cleared via the kidney, leading to increased levels in the setting of decreased GFR [11]. Hepcidin is also cleared from the circulation by hemodialysis [12]. Direct modulation of hepcidin production may be a promising future avenue for treatment of iron restriction in CKD, and current investigational strategies include monoclonal antibodies aimed directly at hepcidin or at the inflammatory stimuli that induce its production, including IL-6 [13].

Definition of Anemia in Children with CKD

The application of adult normative hemoglobin thresholds has been shown to substantially underestimate the prevalence of anemia in children with kidney disease, as normal hemoglobin levels vary by age and sex [14]. Table 1 lists hemoglobin thresholds for the diagnosis of anemia per the 2006 National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI), the 2012 Kidney Disease Improving Global Outcomes (KDIGO) clinical practice guideline for anemia, and the 2017 Renal Association (RA) in the guideline in the United Kingdom.

Evaluation and Treatment of Anemia

Symptoms of Anemia

The clinical presentation of anemia depends on the rate of hemoglobin decline as erythropoietin production slows and the adaptability of the heart and lungs to a decreased hemoglobin concentration. Symptoms of anemia may include fatigue, pallor, somnolence, tachypnea, tachycardia, depression, impaired cognition or muscle function, and loss of appetite. If anemia is more acute from blood loss, patients may experience dyspnea, dizziness, or headache.

Initial Diagnostic Evaluation of Anemia

Prior to initiating treatment with an ESA in anemic children with kidney disease, other potentially correctable causes of anemia should be ruled out, as anemia in children with CKD may not be associated solely with erythropoietin deficiency. A variety of possible causes are listed in Table 2.

Erythropoietin Levels

EPO deficiency is a diagnosis of exclusion. In the setting of normal renal function, plasma EPO

Table 2 Potential causes of anemia in children with chronic kidney disease

Erythropoietin deficiency and/or dysregulation
Iron-restricted erythropoiesis Absolute iron deficiency Functional iron deficiency Impaired iron trafficking
Inflammation and hepcidin upregulation
Chronic blood loss Frequent phlebotomy Hemodialysis circuit losses GI losses Menstrual losses
Acute blood loss Surgical losses GI losses
Uremia and oxidative stress
Hyperparathyroidism and myelofibrosis
Hypervolemia
Nutritional deficiencies B12, folate, carnitine, vitamin C, copper
Medications Angiotensin-converting enzyme inhibitors Nonadherence with anemia therapies Drug toxicity Pure red cell aplasia associated with erythropoiesis stimulating agents
Infectious causes Parvovirus B19-induced aplastic anemia Infection-associated inflammation

levels increase exponentially with decreasing hemoglobin, and values may rise from the normal range of approximately 15 units/liter to as high as 10,000 units/liter [15]. Thus, measuring plasma levels of EPO in children with kidney disease is not useful to clarify the contribution of relative EPO deficiency to anemia, because even if EPO levels are detectable above the normal range, they may still be inappropriately low for the degree of anemia present.

Laboratory Assessment of Iron Status

In clinical practice, the most commonly utilized biomarkers of stored iron remain serum ferritin and transferrin saturation (TSAT). Both ferritin and TSAT have limited sensitivity and specificity to predict bone marrow iron stores and erythropoietic response to iron supplementation. Distinguishing hepcidin-mediated impaired iron trafficking from absolute iron deficiency anemia presents a clinical challenge, as both disorders are characterized by a microcytic anemia with low reticulocyte counts, decreased serum iron concentration, and low transferrin saturation. However, serum ferritin levels can be helpful in distinguishing the disorders; absolute iron deficiency is associated with a low ferritin concentration, while impaired trafficking is characterized by normal or elevated serum ferritin, reflecting iron sequestration in the reticuloendothelial system. In contrast, in patients with functional iron deficiency on ESA therapy, the rate of enteral iron absorption or release from reticuloendothelial cells is inadequate to meet the demands for erythropoiesis; these patients often have low TSAT values with normal or high levels of ferritin, suggesting that patients may benefit from treatment with intravenous iron [16].

TSAT has recognized limitations as well, including diurnal fluctuations and reduction in the setting of malnutrition and chronic disease [17]. There is thus a need for diagnostic tests which more accurately predict the need for or response to iron therapy. A study in pediatric dialysis patients found that the reticulocyte hemoglobin content (Ret-He), which is not an acute phase reactant and reflects iron availability for incorporation into reticulocytes over the previous 2–4 days, performed better than either ferritin or TSAT to distinguish between iron deficiency and sub-optimal ESA dosing [17]. Thus, Ret-He may be an attractive alternative indicator of iron status in clinical practice, although it remains limited currently as it is only measured by flow cytometry [17]. Percentage of hypochromic red blood cells (% HRC) is another laboratory marker of iron status that can assess iron availability for incorporation into red cells. % HRC >6% suggests poor hemoglobin production due to iron deficiency, and may be helpful in distinguishing patients with elevated ferritin levels who may benefit from additional, potentially intravenous, iron supplementation [18]. %HRC also requires flow cytometry for measurement, which may limit its availability in clinical laboratories which measure hemoglobin by electrical impedance and do not have access to the equipment or software required for testing.

Recombinant Human Erythropoietin Therapy

Available Forms of rHuEPO

The human *EPO* gene was isolated in 1985, with commercial production of rHuEPO beginning soon thereafter. Epoetin alfa was approved by the US Food and Drug Administration in 1989 [6]. The development and widespread use of rHuEPO in both adults and children eliminated dependence on red blood cell transfusions which could be complicated by transfusion-associated viral infections, iron overload, and allosensitization [19]. Both endogenous and recombinant EPO have microheterogeneity in carbohydrate structures with variation in sialic acid content, and the molecules with increased sialic acid content demonstrate increased in vivo half-life [20]. The observation that the biologic properties of specific rHuEPO products varied with their molecular structure led to the hypothesis that re-engineering the EPO molecule with the addition of carbohydrate chains, and increasing sialic acid content, could enhance potency and increase half-life. Now there are several types of both short- and long-acting ESA available worldwide, and new formulations continue to emerge requiring ongoing attention to the relative safety and efficacy in children compared to adults.

Epoetin

Epoetin alfa was the first rHuEPO commercialized in the United States, followed by epoetin beta in Europe. Epoetins alfa and beta, both produced in Chinese hamster ovary cells, have minor structural differences but the same physiological effects [20]. There is no definitive evidence of superiority in patient outcomes for any particular epoetin brand. As the patents for the first epoetins expired, biosimilar agents showing only minor differences in clinically inactive components to those of the licensed products emerged and were approved in the United States and Europe; this process will likely continue, leading to wider entry of these agents into the clinical markets [21]. Short-acting epoetin formulations achieve maximum efficacy when dosed 1–3 times weekly and demonstrate a longer half-life when given subcutaneously (19–24 h) than intravenously (6–8 h) [22].

Darbepoetin Alfa

Darbepoetin alfa is an erythropoietin analogue with two additional sialic acid-containing carbohydrates resulting in extended in vivo biological activity. Darbepoetin alfa has been shown to have equivalent efficacy as rHuEPO to maintain hemoglobin when dosed weekly or every other week in children with CKD [23–25]. Darbepoetin alfa may be administered intravenously or subcutaneously, and while the drug clearance, half-life, and bioavailability are similar in adults and children regardless of the route of administration, absorption when given subcutaneously may be more rapid in children [22]. The longer dosing interval inherent to treatment with darbepoetin compared to rHuEPO has made subcutaneous darbepoetin alfa an attractive alternative for anemia management in younger children, with the potential for improving adherence due to the need for less frequent drug administration. A randomized clinical trial in children with CKD stages 4 and 5 demonstrated that darbepoetin alfa is as safe and effective as rHuEPO for the correction of anemia [25]. A longitudinal European registry study similarly demonstrated that children treated with darbepoetin alfa did not experience increased rates of adverse events such as infection or severe hypertension [26]. A potential limitation of darbepoetin alfa in children, however, is the reported discomfort associated with injection. In a blinded, randomized, controlled trial, children who received subcutaneous darbepoetin alfa reported higher levels of post-injection pain by a visual analogue scale compared to those who got epoetin beta, consistent with an increased impression of pain as reported by their parents and nurses [27]. A potential explanation is the more physiological pH of the buffer in the epoetin beta preparation than the darbepoetin alfa preparation [19]. Other pediatric studies have, however, not found pain to be more frequent or severe in patients receiving darbepoetin [25].

Continuous Erythropoietin Receptor Activator

Continuous erythropoietin receptor activator (CERA) is an EPO analog that was created with the integration of a single 30 kDa polymer chain into the EPO molecule, increasing its molecular weight to twice that of epoetin and extending its elimination half-life substantially, to around 130 h [28]. Unlike endogenous EPO and epoetin, which are internalized and degraded following binding to the EPO receptor, CERA escapes degradation by dissociating from the receptor, allowing sustained in vivo efficacy of the compound [29]. A study in children on peritoneal dialysis demonstrated that CERA safely and effectively maintained hemoglobin levels when dosed once or twice monthly, although the doses required to meet goal hemoglobin levels were higher than those required in previously published adult studies [30]. A study in 64 children on hemodialysis aged 6–17 found that CERA given once every 4 weeks was efficacious in maintaining hemoglobin levels with a safety profile consistent with that of adults [31].

ESA Dosing for Children

rHuEPO quantities are traditionally expressed as units, with 1 unit equaling the erythropoietic effect of bone marrow stimulation with 5 μmol of cobalt chloride, an historic treatment for anemia prior to the rHuEPO era [1]. Darbepoetin alfa quantity is expressed in micrograms, with the biological activity of 1 μg corresponding to that of 200 units of rHuEPO [15]. Table 3 lists suggested dosing for ESA agents. The goal after ESA initiation is for a rate of increase in hemoglobin concentration of no more than 1–2 g/dL per month [23].

ESA dose adjustments after treatment initiation should generally not be made until after the first 4 weeks of therapy, and no more often than every 2 weeks in the outpatient setting, as the effects of therapy are not likely to be seen after shorter intervals [23]. Decisions on dosing adjustments should be made based on the hemoglobin rate of rise after initiation, and the stability of hemoglobin during maintenance therapy. When a decrease in hemoglobin is necessary, ESA dose should be decreased but not necessarily held, as a pattern of holding and reinitiating ESA therapy can lead to hemoglobin cycling around the desired target range [32]. Long-acting ESAs like darbepoetin alfa and CERA, with their increased half-life and lower binding affinity for the EPO receptor, stimulate erythropoiesis for longer periods of time and thus may cause higher-than-intended hemoglobin levels in clinical practice. This can be avoided by using lower starting doses and making less frequent dose adjustments than in children treated with short-acting ESAs [33].

Dosing ESA in Children Compared to Adults

The dosing requirements of rHuEPO differ between children and adults. Young children have been reported to require higher weight-related rHuEPO doses than adults, ranging from 275–350 units/kg/week for infants to 200–250 units/kg/week for older children [34]. Despite their lower body weight, children and adolescents on chronic hemodialysis have also been found to

Table 3 Erythropoiesis stimulating agent dosing guide for initiation in children

	Starting Dose	Interval	Route
Epoetin alfa/beta	20–50 IU/kg	3 times per week	SC or IV
Darbepoetin alfa	0.45 μg/kg 0.75 μg/kg	Weekly Every 2 weeks	SC
CERA	4 μg per each prior weekly dose of: 125 IU epoetin 0.55 μg darbepoetin	Every 4 weeks	SC or IV

IU international units; SC subcutaneously; IV intravenously; CERA continuous erythropoietin receptor activator require higher absolute doses of rHuEPO than adults to maintain hemoglobin in goal range [35]. In contrast to typical drug dosing in children which is based on body size to account for a decreased volume of distribution, rHuEPO dose requirements appear to be independent of weight [36]. The potential mechanisms for increased rHuEPO dose requirement in children are not clear, but may include increased presence of non-hematopoietic erythropoietin binding sites (e.g., endothelial, kidney, brain, and skeletal muscle cells) resulting in increased drug clearance, or increased erythropoietin demand during periods of accelerated body growth [15, 34].

HIF Stabilizers

There has been a great deal of interest in the use of HIF stabilizers/prolyl hydroxylase inhibitors (HIF-PHIs) as an ESA-independent treatment for the anemia of CKD, and trials evaluating the efficacy and safety of multiple agents are ongoing. Small-molecule HIF-PHIs modulate HIF-controlled gene products and are capable of inducing endogenous erythropoietin production even in the setting of decreased renal oxygen consumption or even in the absence of kidneys, likely by increasing hepatic erythropoietin production [37]. They can be administered orally in highly bioavailable formulations. Trials in children are in the planning stages, but HIF-PHIs likely represent a promising future treatment avenue in children, particularly in those with ESA-resistant anemia. Longitudinal studies will be necessary to assess for associations between HIF-PHI treatment and risk for potential adverse outcomes including thromboembolic events, oncologic transformation, and pulmonary hypertension.

ESA Hyporesponsiveness

There are patients who, despite iron supplementation combined with escalating ESA dosing, fail to increase hemoglobin levels above 10 g/dL. KDIGO defines *initial* ESA hyporesponsiveness as no increase in hemoglobin concentration from baseline after the first month of appropriate weight-based dosing, and *acquired* ESA hyporesponsiveness as a requirement for 2 increases in ESA doses up to 50% beyond the dose which they had previously required to maintain a stable hemoglobin concentration [23]. An alternative definition is a persistent hemoglobin deficit after 3 months of high-dose ESA treatment (rHuEPO in excess of 400 units/kg weekly or darbepoetin alfa in excess of 1 μg/kg weekly) [38]. While ESA hyporesponsiveness may be chronic, it can also be seen in the context of shorter-term clinical events such as infections or surgical procedures which may negatively impact the response to ESA therapy. Thus, the potential risks and benefits of escalation in ESA dose versus administration of intravenous iron versus red blood cell transfusion in this setting must be assessed for individual patients [23]. Although aluminum-based compounds are used far less frequently in the management of hyperphosphatemia than in the past, awareness of aluminum toxicity is important. Chronic use of aluminum-based antacids and phosphate binders remains the most common cause of aluminum toxicity in patients with ESRD.

Anti-rHuEPO Antibodies

ESA-induced pure red cell aplasia (PRCA) is an increasingly rare hematologic disorder that was first described in the late 1990s. PRCA is characterized by a severe and progressive normocytic anemia, reticulocytopenia, and the almost complete absence of erythroid precursors in the bone marrow, with affected patients becoming transfusion dependent [39]. ESA-induced PRCA is secondary to the development of neutralizing antibodies which block the interaction between an ESA (including epoetin alfa or beta, darbepoetin alfa, or endogenous EPO) and its receptor [39]. Most initial cases of ESA-induced PRCA were seen in countries where epoetin alfa formulated with a polysorbate 80 stabilizer was administered to CKD patients subcutaneously; regulatory advisories have subsequently discouraged this practice [40].

Red Blood Cell Transfusion

Despite best efforts in anemia management, and often in the setting of ESA hyporesponsiveness, patients sometimes do require packed red blood cell transfusion. The decision to transfuse should not be based on an arbitrary hemoglobin level, but rather guided by symptoms and after weighing the specific risks and benefits for the individual patient. Red blood cell transfusions are associated with an increased risk for the development of human leukocyte antigen (HLA) antibodies. In adults, leukoreduction of blood products is an ineffective means to decrease HLA sensitization, and red cell transfusions lead to clinically significant increases in HLA antibody strength and breadth [41]. These antibodies serve as a barrier to future transplantation and may adversely affect graft outcomes [42]. More studies are needed to define the risks associated with red cell transfusion in children with regard to HLA sensitization and graft outcomes.

Iron Supplementation

Targets for Biomarkers of Iron Stores

For all pediatric CKD patients with anemia *not* on iron or ESA therapy, KDIGO recommends oral iron (or IV iron in children on hemodialysis) administration when TSAT is $\leq 20\%$ and ferritin is ≤ 100 ng/ml [23]. For all pediatric CKD patients *on* ESA therapy who are not receiving iron supplementation, KDIGO recommends oral iron (or IV iron in children on hemodialysis) administration to maintain TSAT $>20\%$ and ferritin >100 ng/ml [23].

Oral Iron Supplementation

Most children will require iron supplementation as part of their anemia treatment plan in order to maintain hemoglobin levels and replete iron stores. Children on hemodialysis in particular may have chronic blood loss via the dialysis circuit which exacerbates iron deficiency. Enteral iron supplementation is relatively inexpensive, highly available and generally safe and efficacious in children with chronic kidney disease, although GI side effects of nausea or constipation are sometimes reported. Although true intolerance is relatively rare, it may be a contributing factor to the poor adherence that may arise to prescribed oral supplementation. In addition, co-administration of iron with phosphate binders or antacids can limit absorption due to changes in gastric pH [43]. The usual dosing range for oral iron supplementation is 3–6 mg/kg/day of elemental iron, either daily or divided into two daily doses. The most commonly available oral iron preparations come in ferrous ($Fe2^+$) or ferric ($Fe3^+$) forms, including ferrous sulfate and ferric iron polymaltose complexes [44]. Ferrous sulfate has better bioavailability (10–15%) than ferric iron, and is available in prolonged release forms [44]. Some ferric polymaltose complex formulations are available with added vitamins C, B12, and folic acid to enhance iron absorption and replete other vitamins associated with red blood cell production. However, there is no evidence that ferric iron formulations are superior to ferrous preparations for oral supplementation in children on dialysis.

Intravenous Iron Supplementation

Children on dialysis often benefit from iron preparations administered intravenously due to the poor enteral absorption or poor tolerance associated with oral administration. There are an increasing number of available iron preparations for clinicians opting for intravenous therapy. Early IV iron compounds were formulated as inorganic iron oxyhydroxide complexes, which could result in the release of labile iron directly into the plasma leading to the formation of highly reactive free radicals associated with severe toxicity, including hypotension. Newer preparations surround the iron oxyhydroxide core with carbohydrate shells of different sizes and polysaccharide branch characteristics [45]. The shell characteristics determine how long the iron remains circulating, with larger molecular weight formulations such as iron dextran resulting in longer plasma residence, while products with smaller shells are more labile and likely to release iron directly into the plasma before it can be metabolized in the reticuloendothelial system [46]. Intravenous iron therapy can be delivered as a loading phase, delivered using consecutive doses to replete iron stores, or as smaller maintenance doses given weekly.

Safety of Intravenous Iron

Given trial evidence in adults that higher ESA doses are associated with adverse cardiovascular outcomes, using IV iron to reduce ESA dose requirements is an attractive treatment option. However, the administration of IV iron, even with new formulations, is not without risk. Concerns about potential adverse effects of IV iron supplementation include iron overload, adverse reactions including anaphylaxis, and increased risk when administered in the context of active infections. There have not been any pediatric studies focused on the long-term effects of IV iron supplementation in patients on chronic dialysis. More research to evaluate the effect of differences in formulation and pharmacokinetics of such agents and to determine whether repeated induction of oxidative stress has longer-term sequelae in terms of inflammation and cellular and tissue iron deposition.

Emerging Routes of Iron Supplementation

Ferric pyrophosphate citrate (FPC, Triferic®) was approved by the US FDA in April 2016 for the replacement of iron to maintain hemoglobin in adults on hemodialysis [47]. FPC is dissolved in dialysate and administered via dialysis. In contrast to the IV iron administration of other iron preparations which can lead to the presence of non-transferrin bound iron in the circulation and potentially trigger the generation of pro-oxidant and atherogenic molecules, FPC is quickly transferrin bound and removed from the circulation [48]. Pratt et al. conducted a pediatric study in which FPC was administered via the dialysate (added to bicarbonate concentrate) or intravenously (via the venous blood return line) to 22 hemodialysis patients <18 years of age during dialysis treatment and found it was well tolerated [49]. The mean serum total iron concentrations peaked 3–4 h after administration, and iron exposure based on maximum serum concentration was greater after dialysate administration compared to the intravenous route [49]. Serum iron concentrations were also higher in 12- $<$ 18-year-old subjects after dosing compared to $<$12-year-olds [49].

Ferric citrate is a novel oral phosphate binder which also supplies elemental iron, and has the potential benefit of providing therapy for at least two CKD co-morbidities in a single agent, a potentially adherence-enhancing strategy. The ferric ion in ferric citrate combines with dietary phosphorus in the GI tract, but the excess ferric ions are reduced by the bowel mucosa to ferrous iron and absorbed into the systemic circulation [50]. Ferric citrate has been approved by the US FDA for use in adults, but the safety and efficacy are in the process of being systematically assessed in children with CKD. In a randomized controlled trial conducted in 60 adults with mild-to-moderate CKD (eGFR 15–45 ml/min/1.73 m^2) and iron deficiency (defined as TSAT $\leq$30% and ferritin $\leq$300 ng/ml), 12 weeks of treatment with ferric citrate resulted in more robust increases in TSAT, ferritin, and hepcidin compared to ferrous sulfate treatment [51]. No differences in either mean change in hemoglobin or adverse events were noted between groups, with the most common reported adverse event gastrointestinal complaints [51].

Anemia after Successful Renal Transplantation

Post-transplantation anemia (PTA) is a frequent complication among both adult and pediatric kidney transplant recipients and is usually more common immediately after transplantation in spite of early stabilization of graft function. Depending on time after transplantation *early PTA*, usually defined as anemia which develops up to 6 months after transplantation, can be distinguished from *late PTA*, defined as anemia which develops after 6 months [52]. Causes of and risk factors for PTA are multifactorial and are summarized in Table 4.

Table 4 Risk factors for early and late post-transplantation anemia (PTA)

Early PTA (<6 months)	Late PTA (>6 months)
Pretransplant anemia	Early PTA
Iron deficiency – poor nutrition	Impaired GFR
depletion of iron stores before Tx	Iron deficiency
surgery blood loss	Maintenance immunosuppression (MMF, AZA)
frequent blood samples	Ace-inhibitors
Induction immunosuppression	Acute rejection
Virus and bacterial prophylaxis	Infections
Infections	Comorbidities
Delay graft function	Chronic inflammation
Acute rejection	Hyperparathyroidism
Hyperparathyroidism	
Female gender	
Younger age	

Clinical Outcomes

PTA has been associated with multiple long-term outcomes: all-cause mortality, decline in estimated eGFR, allograft dysfunction and loss, left ventricular hypertrophy, and congestive heart failure [53]. Many retrospective and a few prospective adult studies have investigated and confirmed the association between PTA and mortality and graft failure [54]. Anemia may contribute to hypoxic damage secondary to reduced oxygen delivery to the tubulointerstitium which stimulates further production of proinflammatory and profibrotic molecules, perpetuating chronic allograft injury [55]. Anemia has been identified as an independent risk factor for the development of left ventricular hypertrophy and de novo congestive heart failure, both strong predictors of mortality among kidney transplant recipients. Even modest reductions in hemoglobin are recognized as hemodynamic stressors that promote ventricular growth and remodeling, ultimately causing left ventricular dilation and likely contributing to increased cardiac mortality [56, 57].

Evaluation and Prevention of PTA

The initial diagnostic work-up of PTA is similar to that suggested in pre-transplant CKD (Table 2). Transplanted patients should be screened frequently for anemia. Recommendations include at least weekly for months 1 to 2, at least every other week for months 3 to 4, at least monthly for months 4 to 12, and then at least once every 3 to 6 months [58] in order to start early treatment and improve prognosis [53]. Effective management of pre-transplant anemia may prevent the development of PTA. Implementation of anemia treatment to properly prepare candidates for kidney transplantation protects against the consequences of intraoperative blood loss and hemodilution, which includes the need for post-operative blood transfusions [59].

Treatment of PTA

Considering its multifactorial nature, PTA treatment may be challenging and should be directed to the underlying cause. There are not specific recommendations for anemia treatment in transplanted patients and PTA is usually treated in the same manner as anemia in CKD. Treating mild and severe anemia in patients >3 months following successful transplantation may increase their survival probability and reduce the rate of decline of GFR [60]. There is no contraindication to ESA therapy for the treatment of PTA [61]. Despite a high prevalence of anemia post-transplant, the number of patients receiving ESA therapy in the post-transplant period is low, less than 10% [62] and the optimal timing of initiation and the effectiveness of ESA therapy has not been defined. In this setting, the presence of significant interstitial fibrosis and tubular atrophy on transplant biopsy may be a useful indicator of the need for ESA treatment [63]. Every effort should be made to reduce the need for red cell transfusions in renal transplant recipients. Adverse consequences of perioperative transfusions include the development of donor specific antibodies, with antibody-mediated rejection more frequently detected in transfused patients than in non-transfused recipients [64].

Abstract

Overhydration and dehydration remain a difficult balance to maintain for children with chronic kidney disease (CKD). For clinicians managing children with CKD, especially those on dialysis, an accurate assessment of volume continues to be one of the most difficult issues and one that needs regular evaluation to maintain optimal sodium and water homeostasis. Traditional tools including clinical history, physical examination, and measurement of blood pressure may not provide an accurate assessment of fluid overload, which remains one of the main drivers of arterial hypertension

in children with CKD and those receiving kidney replacement therapy (KRT). Various techniques have been proposed to assess volume accurately in these patients including single- and multifrequency bioimpedance analysis and, for children on hemodialysis (HD), blood volume monitoring. Both have gained much attention over the past few years, while limited experience and scarce data are available for lung ultrasound, inferior vena cava echography and use of N-terminal pro-brain natriuretic peptide in children with severe CKD and those requiring dialysis. For the clinician, it remains important to remember that patients often have a combination of etiologies (e.g., volume overload and increased renin). A detailed clinical history and examination, supported by serial measurements using one or more of the above techniques of volume assessment, can guide management and maintain the child in an euvolemic state, avoiding the deleterious effect of fluid excess or depletion. Currently, no single technique can be considered as gold standard, but each method, at best, contributes to improving volume assessment when repeated over time on the same patient.

Introduction

Childhood chronic kidney disease (CKD) is a devastating illness requiring lifelong medical input, and despite improved survival, those receiving kidney replacement therapy (KRT) continue to display excess morbidity and mortality secondary to cardiovascular (CV) disease [1, 2]. Longitudinal studies report that ~45% of deaths are from CV disease, increasing to 57% in children on hemodialysis (HD) [3, 4]. In children with nondialysis CKD, left ventricular hypertrophy (LVH) is common and occurs early in the disease process with reported prevalence of up to 65% and increasing to 82% in those on HD [5, 6]. Arterial hypertension is observed in >50% children [7, 8], and uncontrolled or difficult to control hypertension is one of the major risk factors for cardiovascular disease in this cohort. Available longitudinal data for children on long-term KRT largely describes a progressive deterioration in cardiac structure and function with increasing time on dialysis, with few data showing improvement [9, 10].

Optimal management of sodium and water homeostasis is a priority in children with CKD and in particular for those on dialysis. Both water and sodium are major components to be considered when performing a comprehensive evaluation of a patient's volume status [11]. Similar to the general population in whom dietary salt reduction has been shown to lower blood pressure (BP) and CV risk, in adults receiving chronic dialysis, salt reduction has also been shown to be associated with systolic and diastolic BP reduction [12]. The assessment of sodium balance is very difficult to obtain in clinical practice, and volume assessment is usually restricted to fluid status evaluation. It is however important to recognize that reduction in sodium intake is essential to the reduction in the patient's interdialytic weight gain (IDWG).

The majority of childhood etiologies causing CKD are "salt losing," and as opposed to adults, more children on KRT remain polyuric. Despite this, most children, once started on dialysis, will experience a reduction in urine output and develop relative oliguria or become anuric [10]. Assessment of the euvolemic status in a child on dialysis relies on the identification of so-called dry weight, that is, the optimal body weight to be aimed for at the end of a dialysis session. For clinicians, this remains one of the most challenging aspects in children with end-stage kidney disease (ESKD) management, with major obstacles faced as a result of the low sensitivity of clinical markers and the lack of a gold standard method or even a clinically reliable method of sufficient accuracy to estimate fluid overload across the childhood age range. In contrast to adults on dialysis, additional peculiarities of the pediatric population include challenges around the clinical evaluation of young children, limitations in their ability to tolerate investigations, changing body composition with growth through childhood, and rapid changes in hemodynamic measures when unwell. This underscores the major clinical relevance of the assessment of fluid status in a dialysis-dependent child.

The goal of sodium and water management in children with CKD is to keep the child in the narrow window between volume overload and volume depletion. Both conditions are associated with significant complications, and both can lead to a reduced quality of life and even increased mortality in CKD. Given the low level of evidence from current studies in children, no clear consensus exists concerning the optimal technique of volume assessment in the pediatric CKD population.

The management of volume overload in children on peritoneal dialysis and HD is discussed under the relevant chapters.

Consequences of Volume Overload

Patients with oligoanuric CKD and those on dialysis develop an increase in extracellular volume as a consequence of the loss of renal regulation of salt and water. The resultant cardiovascular complications include not only hypertension, LVH, and large arterial disease [1, 13] but also cardiac failure and pulmonary edema in cases of severe volume overload. In children treated with dialysis, both post-dialysis fluid overload and IDWG remain significantly correlated with BP and markers of cardiac and vascular health, although the data remain conflicting likely due to small patient numbers [14, 15]. Other possible consequences of volume excess include increased inflammation, loss of appetite, and malnutrition. This risks progression is a vicious cycle linking volume overload, reduced appetite, and resultant loss of "real" body weight. As these changes can be difficult to assess clinically, this may result in further worsening of volume excess and thus should always be kept in mind in patients on dialysis, and dry weight should be adjusted regularly. Furthermore, if a high ultrafiltration (UF) rate is prescribed in case of severe fluid overload, it carries a risk of hypovolemia and its consequences that are described below.

Consequences of Excessive Volume Depletion

Hypovolemia is common in children with salt-wasting nephropathies, those treated with diuretics, and those in whom UF is performed during dialysis. Hypovolemia may be associated with several acute symptoms, including asthenia, fatigue, dizziness, cramps, nausea, and vomiting. Intradialytic hypotension can cause hypoperfusion of several organs, including the brain, eyes, gut, kidneys, and the myocardium. The loss of residual kidney function is a particularly dramatic complication given the superiority of kidney clearance over dialytic clearance on uremic toxins and the importance of residual kidney function in volume management itself. Myocardial stunning, a segmental decrease of myocardial contractility, occurs in the majority of HD sessions even in children [16]; it is more common when high ultrafiltration rates are used, and in the long term, it may be associated with severe cardiac impairment, as myocardial hibernation and fibrosis. Brain hypoperfusion has been associated with watershed infarctions in patients on HD undergoing intradialytic hypotension [17]. Anterior ischemic optic neuropathy is a rare but dramatic complication for patients undergoing PD, characterized by infarction of the optic nerve head due to hypoperfusion of the posterior ciliary arteries and causing sudden blindness, usually driven by hypotension [18].

Access malfunction and thrombosis are other possible complications of hypovolemia in children treated with HD, which deserves attention given the importance of preserving vascular access in children with a foreseeable long period of KRT ahead.

Clinical Assessment of Volume Status

History and Physical Examination

Clinical assessment remains of utmost importance in children with CKD and those receiving dialysis. For those on dialysis, a "dry weight" is defined as the lowest weight a patient can tolerate without the development of symptoms or hypotension. It is, at best, an estimate and needs constant evaluation and regular adjustment, particularly in the growing child. Readjustment of a child's dry weight is usually based on a combination of clinical assessment, evaluation of events during dialysis, and investigations to assess volume using some of the methods described later. Physical examination should include evaluation for the presence of edema, degree of filling of the jugular vein, and lung auscultation. It is important to remember that edema is often not clinically evident until the extracellular fluid overload has exceeded 10% of body weight [19]. Although important, the clinical assessment may be grossly misleading, particularly in less experienced hands, and should not be considered sensitive enough on its own to provide an adequate assessment of volume in children with CKD.

It is essential to regularly review the child's 24-h urine output. This should be clearly documented at the time of commencement of dialysis and ideally repeated at 3-monthly intervals as it is likely to reduce over time. Based on urine output, patients can be categorized as either anephric, oliguric (<300 ml/m^2/day), normal, or polyuric (over 2 l/m^2/day). Despite its clinical utility, 24-h urine output is often difficult to collect or not possible especially in the youngest patients. Insensible fluid losses calculated at 400 ml/m^2 body surface area should be taken into account to obtain an accurate fluid balance. Fluid allowance should be clearly documented and regularly discussed with the child and their caregivers. Weight gain between HD sessions, called IDWG, is ascribed to be secondary to fluid gain between dialysis sessions [20] and is a simple measure of intermittent volume gain in patients receiving intermittent maintenance HD. In small studies in children receiving HD, IDWG has been shown to correlate with BP and left ventricular mass index, and those with a median IDWG $>4\%$ of body weight are at higher risk of LVH [14].

The occurrence of any event potentially leading to weight loss (e.g., intercurrent infections, diarrhea, and vomiting) or weight gain (e.g., acute kidney injury resulting in reduction in urine output) should be investigated comprehensively. In the same way, any symptoms of volume excess and depletion should be looked for, as previously described. An accurate fluid balance, taking into account fluid intake and changes in 24-h urine output, should be performed. An assessment of appetite, including an evaluation of dietary intake of energy and protein and the change in intake, may be of help in interpreting or predicting changes in body weight. When unwell, changes in *true* body weight can be particularly rapid in young children receiving dialysis and especially in those who may have restricted diets or those dependent on protein and calorie supplementation for their nutrition. The clinician will often need to "reset" the target "dry weight" to avoid the inevitable water logging and consequent hypertension.

Blood Pressure

An accurate assessment of BP is critical, but some issues should be considered further. Firstly, 24-h ambulatory BP measurement (ABPM) remains the gold standard method for accurate assessment of hypertension in this population with a high prevalence of masked hypertension [10]; interdialytic 44-h ABPM may provide even more information than 24-h ABPM in diagnosing hypertension in pediatric patients on maintenance HD [21], although tolerance of these and repeat measurements in the pediatric population are less likely to be successful and therefore not widely used in clinical practice but should be considered in individuals with difficult or resistant hypertension. While desirable, ABPM cannot be performed in the youngest patients on dialysis and those with limiting comorbidities. Home BP may be a possible alternative, with higher agreement with ABPM compared to office BP [22]. In particular, intra- or post-dialytic BP should be viewed as markers of dialytic stability only, as they do not accurately reflect the true BP level of the patient.

Next is the complex relationship between volume and BP. Hypervolemia as a result of excess fluid intake or inadequate removal of salt and water during dialysis remains one of the most important mechanism underlying increased BP levels. Although a number of mechanisms have been implicated in adult dialysis patients, including activation of the renin-angiotensin-aldosterone system (RAAS) and the sympathetic nervous system, endothelial dysfunction resulting in abnormalities of nitric oxide production, and vascular stiffening, hypervolemia in children is considered the primary mechanism by most experts [23]. Even in patients with volume overload, the lag phenomenon should be considered: this is the delay in BP reduction after normalization of volume status, due to vasoconstriction. The opposite phenomenon has also been observed, in that fluid loading does not necessarily acutely raise BP. Some patients have normal BP despite hypervolemia, although in the published literature the assessment of this hypervolemia has not been systematically demonstrated and it is unclear if this equates to an "increased intravascular volume." In this scenario, the BP may be viewed as an important index, but basing management decisions on BP values alone may be misleading: the presence of hypertension does not necessarily denote euvolemia, and normotension does not necessarily exclude volume overload. A particular case is the so-called phenomenon of drug-resistant hypertension in children with ESKD, which should be considered volume-dependent until proven otherwise. Finally, other causes of relevance in the child receiving dialysis should be considered. For example, in those with an underlying glomerular disease, hypertension may be disproportionate to the degree of volume loading and secondary to excess renin production. Importantly, a patient with impaired left ventricular systolic function may not be hypertensive despite significant fluid overload.

Techniques to Assess Fluid Status

Given the limitations of clinical parameters in the assessment of volume status, it is essential to rely on technology to improve fluid evaluation. Among the various proposed techniques, bioimpedance analysis (BIA), blood volume monitoring (BVM), lung ultrasound (LUS), inferior vena cava (IVC) echography, and N-terminal pro-brain natriuretic peptide (NT-proBNP) are currently widely used in pediatric nephrology centers. Some of these methods aim at measuring intravascular volume (BVM, IVC diameter, BNP), while other techniques assess total body water or extracellular water. None of these methods can be considered gold standard techniques: the main advantages and limitations of each technique are summarized in Table 1.

Bioimpedance Analysis (BIA)

BIA is a noninvasive bedside technique for the assessment of body composition. Two main approaches have been proposed: single-frequency and multifrequency BIA. Single-frequency BIA uses an impedance plethysmograph that emits

Table 1 Comparison of techniques for assessment of fluid status in children with CKD

800 mcA and 50 kHz alternating sinusoidal currents. With the subject in a supine position, the outer electrodes are placed on the proximal, dorsal surface of the third proximal phalanx of the right hand and foot and the inner electrodes on the wrist and ankle in such a way as to leave at least 5 cm of free skin around the outer electrodes. Impedance is measured and its components resistance (R) and reactance (Xc) given as output measures. Resistance (which represents the opposition to flow of an alternating current through intra- and extracellular ionic solutions) is relatively low in lean tissues, which contain large amounts of water and electrolytes, and relatively high in adipose tissue and the bone. Reactance, the opposition to flow of an electric current due to capacitance, is produced due to the insulating effect of cell membranes, which act as capacitors. Thus, both indices increase as body water decreases and vice versa. Values of R and Xc can be used as absolute values or placed in a vector plot. Although some reports show that single-frequency BIA could help in improving dry weight assessment in children on dialysis [24, 25], this technique is not widely used, mainly due to difficulties in the interpretation of the data. Multifrequency bioimpedance, and in particular BIA spectroscopy (BIS), consists in the measurement of impedance through a wide range of frequencies, thus allowing for the differentiation between extracellular and intracellular compartments and, by means of predictive equations, the estimation of body compartments, in particular extracellular water, intracellular water, and relative overhydration.

Given its simplicity, BIS has gained popularity in recent years. Although some trials, even in children, have shown a significant correlation between BIA estimates and other markers of hydration [26], a constant finding in the literature is a good agreement at a mean population level but poor individual-level agreement between reference methods and BIS [27, 28]. An attractive clinical utility for BIS would be to evaluate its agreement with IDWG, but these are poorly correlated and thus not currently useful in the estimation of the degree of overhydration. Huge discrepancies have also been found in some cases between BIA estimates and reference techniques, like deuterium bromide dilution technique, so great caution is always needed when using BIA results to determine a patient's dry weight [27]. In general, BIS studies show better accuracy in healthy children than in patients on dialysis. Further studies are needed to better understand the role of BIA in children with CKD. As a general rule, the longitudinal analysis of BIA data in the same patient seems the best strategy for its use.

Blood Volume Monitoring (HD Only)

This technique describes the continuous monitoring of blood volume (BV) changes during an HD session and is based on the measured changes of hematocrit, hemoglobin, or total protein levels of the patient during UF. Relative BV reduction during HD depends on UF rate and refill capacity, the latter depending mainly on plasma oncotic pressure and hydrostatic pressure, which is proportional to tissue hydration: in the situation where the UF rate exceeds refill capacity, hemoconcentration occurs and BV decreases. Most modern HD machines have integrated blood volume monitors that provide a continuous curve representing the percent blood volume change during the session, although the ability to perform BVM may be limited when using the smallest caliber lines and in some older HD machines.

One of the main problems with BVM is that, although some pediatric reports showed that UF with a BV change <8%/h during the first hour of dialysis and <4% thereafter is usually safe, the high inter-patient variability makes it impossible to define a specific threshold, which fits all patients. The shape of the BV curve is probably more informative. In the majority of asymptomatic HD sessions, a common pattern is seen: an initial drop in BV, followed by a plateau, which reflects a perfect balance between UF and refilling. A flat curve, without any reduction of BV, is usually suggestive of volume overload, while a continuous decrease of BV without stabilization suggests very rapid UF and is often associated with intra-HD morbidity (Fig. 1). Both increasing tachycardia and a steeper BV fall in

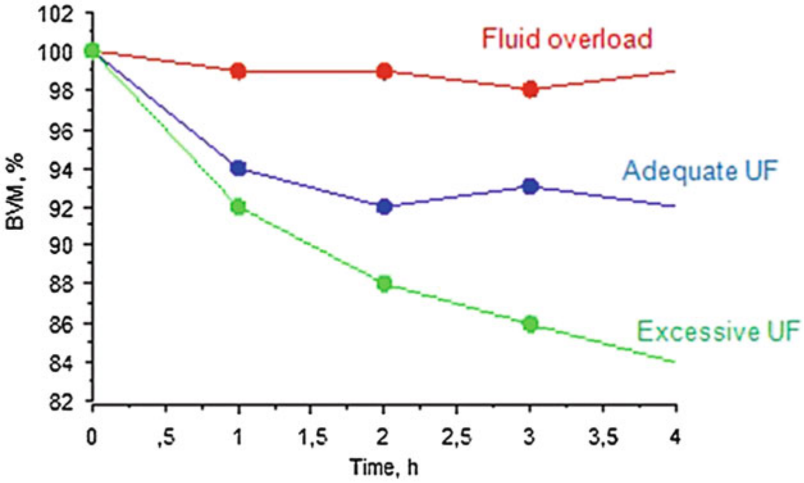

Fig. 1 Typical blood volume monitoring curve shape in case of appropriate ultrafiltration, volume overload, and excessive fluid removal during hemodialysis

the first hour of dialysis have been reported to be associated with hypotension, with or without symptoms [29].

Many studies have demonstrated that the use of BVM in children on HD is associated with better BP control and a lower left ventricular mass index, suggestive of better volume control, and with reduced incidence of intradialytic symptoms [29–31]. This technique can therefore be considered an essential tool to guide UF in children treated with HD.

One of the major advantages of this technique is to have the ability to monitor intravascular fluid volume during an HD session and therefore to provide a more patient-centered therapy. Currently, none of the other techniques allow this to be performed "intra-dialysis" in a practically feasible way but are limited to a pre- and post-dialysis session assessment.

Inferior Vena Cava Echography

Ultrasound assessment of IVC parameters was proposed as a tool to estimate intravascular volume. The end-expiration (maximal) and end-inspiration (minimal) IVC diameters can be measured and the IVC collapsibility index calculated as (maximal diameter − minimal diameter)/maximal diameter. The measurements can be normalized to body surface area and compared with the proposed reference values for healthy children. A decrease of IVC diameter and a reduction of collapsibility index have been shown in children treated with PD or HD after fluid removal, but the reports investigating the role of this technique in fluid assessment are conflicting [32–34]. The main limitation of IVC ultrasound is its low reproducibility and the need to be performed by highly skilled personnel. A second limitation is that it looks at the intravascular compartment only, which is poorly correlated with total body water. Third, the high inter-patient variability makes it difficult to interpret a single IVC diameter value but requires serial measurements.

Lung Ultrasound

The rationale for adopting ultrasound to measure lung water is that water accumulation in the lung interstitium thickens the interlobular septa. This thickening produces a reverberation of the ultrasound beam and generates visible bundles at narrow basis going from the probe to the edge of the echotomography screen: these artifacts are known as "B-lines," and their number is correlated with the amount of extracellular lung water in adults. B-lines can be seen on LUS before lung congestion becomes clinically detectable by auscultation or chest X-rays. B-lines were usually quantified in 14 intercostal positions on the anterior and lateral chest wall for patients weighing under 20 kg and 28 positions for patients over 20 kg.

Recent trials in adult patients with ESKD demonstrated a strong correlation between the number of B-lines and various echocardiography parameters including left atrial volume, pulmonary artery pressure, and ejection fraction and, even more importantly, with both the risk of mortality and cardiovascular complications [35, 36]. The experience in children is so far limited to a couple of studies involving children treated with dialysis, which found a good sensitivity of LUS in detecting subclinical fluid overload [37, 38]. Some important advantages of this technique are its ease of learning and the acceptable inter-observer variability. Unfortunately, LUS is unable to discriminate euvolemia from underhydration. Further studies are needed to better understand how to use this technique to assess dry weight in children.

N-Terminal Pro-brain Natriuretic Peptide (NT-proBNP)

NT-proBNP is synthesized and released from the ventricular myocytes in response to increased ventricular wall stress. Increased left ventricular volume or pressure overload, such as occurs in congestive heart failure and hypertension, enhances the secretion of NT-proBNP from the ventricle. NT-proBNP is a strong predictor of heart failure and mortality in adults with ESKD. Its association with fluid status in adults is still under debate, but according to the available evidence, it should be considered a poor volume marker in this population [39, 40]. The role of NT-proBNP in children on dialysis has been poorly investigated, with conflicting results [25, 41]. At present, there is no published evidence to support its use as a volume marker in children with CKD, and further data are needed.

Conclusions

Fluid status assessment is an essential step in the management of children with ESKD, particularly in those on dialysis. History and physical examination, together with BP assessment, are of utmost importance but not sensitive enough to capture early changes in volume status. Several techniques have been proposed, but this remains largely an underexplored area, and to date, no technique is accurate enough to be considered gold standard. A comprehensive evaluation, including a combination of methods described above, is recommended. For the clinician, it remains important to remember that patients often have a combination of etiologies (e.g., volume overload and increased renin) and that it is important to have a detailed understanding of the temporal events leading to the clinical issue at hand to help keep the child euvolemic and to avoid the deleterious effect of fluid excess or depletion.

Abstract

Peritoneal dialysis (PD) is currently the most commonly used kidney replacement therapy (KRT) in children worldwide. In this chapter, the fundamentals of peritoneal water and solute transport are detailed, including a description of peritoneal membrane function and transport characteristics. The types of dialysis fluid and their impact on membrane preservation over time on chronic PD and the basic concepts that impact dialysis modality choice are presented. Factors influencing timing of dialysis initiation and choice of catheter and other dialysis equipment, as well as remote patient monitoring options, are reviewed. Once PD is initiated, the dose of dialysis delivered should be measured, typically by measuring urea clearance relative to solute distribution volume (Kt/V). The prescription should be tailored based on the patient's peritoneal membrane characteristics as measured through the peritoneal equilibrium test (PET) and considering the intraperitoneal pressure. Determination of the adequacy of the dialysis procedure should also consider nutritional status, growth, and the general well-being of the patient, in addition to the correction of the metabolic derangements of chronic kidney failure. The PD procedure must be carefully monitored to avoid common and potentially life-threatening complications. Catheter exit site infection and peritonitis are among the most important complications that require ongoing monitoring, and this chapter reviews guidelines for preventing and treating these complications. Common catheter and dialysis procedure-related complications are discussed; patient outcome on chronic PD and promising perspectives are presented.

Introduction

Peritoneal dialysis (PD) is the predominant initial dialytic modality for children with kidney failure [80] based on several advantages. It can be utilized in any age group including neonates and young infants. Catheter placement is simple as compared to the vascular access required in hemodialysis and is not associated with needling-related fear and pain. Cardiocirculatory stability is superior without an extracorporeal blood circuit and lower ultrafiltration rates. PD provides a greater degree of freedom, hospital visits are infrequent, and compatibility with social life and school attendance is good. Except for infants and young children, routine follow-up in the dialysis centers is usually required once per month. On the other hand, home PD requires significant medical and technical knowledge and encumbers families with major responsibility. The PD procedure appears straightforward but requires in-depth knowledge of the technique, treatment targets, and complications; close interaction between families and experienced members of the dialysis center is essential. This chapter reviews current knowledge of the principles of PD, timing and equipment for implementation of dialysis, and determinants of adequacy, biocompatibility, complications, and outcomes of the PD treatment. It moreover provides an overview on recent technological and therapeutic advancements.

Principles of Peritoneal Solute and Water Transport

The function of PD is determined by the peritoneal membrane characteristics and the peritoneal dialysis fluid. The peritoneum lines, the inner surface of the abdominal wall, cover the intraperitoneal organs, the visceral mesentery, and the omentum. The peritoneal membrane surface area is roughly equal to the body surface area. According to computed tomography studies, only 30%–60% of the peritoneal membrane is in contact with dialysate [19] depending on the fill volume. The primary surface in contact with PD fluid is the mesothelial cell monolayer, which has numerous local homeostatic functions and secretes surface-active substances and lubricants such as CA125 to prevent frictions. Microvilli increase the functional peritoneal surface area.

The submesothelium is 150–450 μm thick and contains blood capillaries, lymphatics, and nerves, which in the healthy peritoneum are mostly located within three distinct layers [96]. The primary barrier that solutes and water have to cross is the capillary endothelial cells, which are linked to each other by junctions. Solute transport occurs via the paracellular and the transcellular route. About one-third of the submesothelial vessels are lymphatics, vessels which reabsorb fluid and (macro-)molecules from the interstitium to the systemic circulation. The submesothelial space consists of extracellular matrix, i.e., collagen bundles, hyaluronan and mucopolysaccharides, few fibroblasts, and isolated inflammatory cells. Its role in transport is minor unless significant submesothelial fibrosis has developed with chronic PD, which reduces the osmotic conductance of glucose. The role of the mesothelial barrier in solute and water transport has not yet been established but may be low [29, 45, 61].

Peritoneal capillary blood flow has been reported to vary between 100 and 150 ml/min in adults and is relatively higher compared to other tissues. PD solute transport appears to be preserved even in moderately hypotensive patients [91]. Transport characteristics as described in the peritoneal equilibration test (see section "The Peritoneal Equilibrium Test") primarily depend on the microvessel density of the peritoneum [95]. Newborns and infants have a higher peritoneal vessel density, which explains the higher solute transport and the need of higher dialysate glucose concentrations to achieve adequate ultrafiltration in this age group. Permeability increases during acute peritonitis, possibly due to increased vessel density, and progressively declines with increasing peritoneal fibrosis. Increased lymph vessel density increases solute and water reabsorption.

Peritoneal dialysis fluids contain high concentrations of glucose as the osmotic agent to remove water together with solutes, a buffer for correction of metabolic acidosis and electrolytes to maintain electrolyte homeostasis. Novel PD fluids may contain bicarbonate buffer and icodextrin or amino acid as the osmotic agent. The driving forces of solute and water transport between the dialysis fluid and the capillary are diffusion, osmosis, and convection. Diffusion along a concentration gradient and across a semipermeable membrane such as the peritoneum is called osmosis. The concentration gradient between blood and dialysate is maintained by exchanging the dialysate. It also depends on the residual dialysate volume, i.e., the dialysate remaining intraperitoneally after drainage. Average residual dialysate volume is about 8% of a dwell volume of 1000 ml/m^2 BSA [101], but this may vary considerably from dwell to dwell and between patients. It increases considerably in patients with intra-abdominal adhesions. In such cases, solutes retained within the residual fluid diminish the concentration gradient. This may be especially relevant with cyclers reducing the fill volume with insufficient drainage of the preceding dwell.

Diffusion is a size-selective process; small molecules such as urea and creatinine diffuse faster than larger molecules such as vitamin B12, the so-called middle molecules. Phosphate transport is slow due to a surrounding aqueous layer increasing the effective molecular weight. Solute transport depends on size, chemical and electrical properties, and the abundance and function of intercellular junctions and transmembrane transporters, which collectively define the permeability of the membrane.

The peritoneal transport characteristics can well be described based on a three-pore model [90]. The ultrasmall pores correspond to the water-selective aquaporin-1 (1%–2% of all pores, radius 2–4 Å), while the molecular counterparts of the abundant small pores (90%–95%, 40–60 Å) and large pores (5%, radius 200–300 Å) have not been defined yet. Forty to fifty percent of water transport, and thus ultrafiltration, occurs via the aquaporins, 50%–60% via the small pores, while water transfer via the large pores is negligible. Fluid transport is determined by the crystalloid pressure exerted by the glucose. In the early phase of a dwell, the high concentrations of glucose removes water primarily via water-selective aquaporine-1, which results in a transient decline in solute concentrations of the dialysate, so-called sodium sieving [61]. During the later phase of the dwell, small pore function predominates, and solute concentration increases again in the dialysate. Icodextrin-based solutions contain starch-derived polymers, which create a colloid osmotic pressure removing water and dissolved solutes via the small pores. This is a slow process, but since icodextrin resorption rate is low, osmosis is maintained for 8–12 h. Sodium sieving does not occur.

Small hydrophilic solute transport occurs almost exclusively by concentration gradient-driven diffusion across the small pores and by convection, i.e., the solutes dragged together with the ultrafiltration; therefore, convective purification depends on the amount of UF achieved. The movement of proteins and other macromolecules occurs across the large pores and is driven by hydrostatic forces.

Solute removal further depends on the effective peritoneal surface area, i.e. the total membrane pore area available for peritoneal transport. It increases with dialysate volumes between 800 and 1400 ml/m^2 BSA and is one-third higher in the supine than in the upright position [38], but is not different with neutral pH, double-chamber PD fluids as compared to acidic, single-chamber fluid [102].

Ultrafiltration consists of the bulk movement of water together with permeable solutes dragged along across the peritoneal membrane (convective mass transfer). The primary driving force is the osmotic pressure of dialysis fluid exerted by glucose or icodextrin. The effect of the hydrostatic pressure gradient is usually small unless the intraperitoneal pressure is high (see section “Standardization of Dwell Volume”). Other factors that affect ultrafiltration are the functional membrane surface area recruited and its hydraulic permeability and reabsorption of fluid into the surrounding tissue via lymphatic vessels. In adults on PD, lymphatic fluid absorption is low [115] but increases substantially with declining ultrafiltration capacity [106].

Choice of PD

The International Society for Peritoneal Dialysis (ISPD) practice recommendations suggest that dialysis modality selection in children should be influenced by child/parent/caregiver choice, the age and size of the child, the presence of comorbidities, modality contraindications, expertise of the dialysis team, and the support available for the child and caregiver [15].

Although there are no prospective studies directly comparing outcomes among children receiving maintenance hemodialysis (HD) and PD, PD is the most common dialysis modality used for children worldwide, particularly in emerging countries where access to the dialysis equipment and staff required to perform HD may be limited [13, 15, 23, 56]. PD is particularly advantageous in infants and small children as it avoids the need for a vascular access, which may be difficult to achieve and/or maintain in this age group. PD also avoids the need for exposure to the anticoagulation often required during HD. Studies suggest that children on PD may lose residual kidney function (RKF) more slowly than those maintained on HD [36, 73]. Compared to in-center HD, the timing of the dialysis procedure is more flexible with PD, which may promote participation in family, social, and school activities.

ISPD recommendations appropriately emphasize that the burden of care for children on home dialysis therapies, including PD, must be considered during modality selection [15]. Responsibilities for the caregiver includes care of the PD catheter, performing the dialysis procedure, medical decision-making (e.g., choosing concentration of glucose, screening for infection), and assessing and addressing any technical issues or alarms if an automated cycler is used. ISPD guidelines suggest that formal assessment of the child's and caregiver's perception of quality of life may inform this process [48, 128].

Contraindications to PD include the presence of an abdominal wall or peritoneal membrane defect, e.g., omphalocele, gastroschisis, unrepaired bladder exstrophy, and diaphragmatic hernia. Extensive peritoneal membrane scarring from previous intra-abdominal surgery, with resultant peritoneal membrane failure, also excludes PD as a dialysis modality. Relative contraindications include the presence of ileostomies and colostomies, as an analysis of the International Peritoneal Dialysis Network (IPDN) revealed that among children on PD enrolled in that registry, the presence of a colostomy was associated with an increased risk for peritonitis [20]. Adequate PD may be difficult to achieve in infants and small children with significant intra-abdominal organomegaly [15].

Initiation of Peritoneal Dialysis and Dialysis Equipment

The right time to begin kidney replacement therapy (KRT) and the technical issues are key factors ensuring a safe journey to kidney transplantation, with normal growth and optimal cognitive development.

Initiation of Dialysis

There is no single criterion for deciding the right time to start dialysis for children with CKD. The most commonly used parameter has been an estimated glomerular filtration rate (eGFR) of less than 10–15 ml/min/1.73 m^2 [59]. A recent analysis of data from the US Renal Data Systems (USRDS) demonstrated an increasing percentage of children initiating dialysis at eGFR higher than 10 ml/min/1.73 m^2. Studies from USRDS and the European Society for Pediatric Nephrology/European Renal Association-European Dialysis and Transplant Association Registry show no clinical benefit in children initiation of PD at higher eGFR, but these studies cannot completely control for clinical indications for dialysis initiation that might also influence outcomes and the imprecision of the estimating equations utilized to calculate GFR. The recently published ISPD guidance suggests initiating dialysis in children at an eGFR of less than 10 ml/min/1.73 m^2 or in the presence or uremic symptoms that are refractory to medical care [15]. In children, biochemical variables like hyperparathyroidism, acid-base status, electrolyte imbalance, anemia, and clinical variables like growth, hypertension, cardiovascular status, residual kidney function (RKF), cognitive development, and school performance should all be carefully considered [83]. However, the high tolerance in children to those imbalances could be misleading, and the potential negative impact of the uremic milieu on growth and cognitive development reinforces the concept of using eGFR as a guide to dialysis initiation. In addition, recent studies suggest that the rate of RKF decline, a key parameter of outcome, may be reduced following initiation of PD, compared to the pre-dialysis period [35, 50].

A detailed assessment of the learning ability and educational level of the parent or caregiver is an important point to evaluate before starting PD therapy. The dialysis team should individualize a training plan for the proper training of adults who will perform the procedure at home. The risk of potentially preventable complications particularly exit site infections and peritonitis has been well documented when an adequate training program has not been implemented. The ISPD guidelines 2012 update [127] emphasizes important points related to caregiver training, including that PD training be conducted by a PD nurse with pediatric training experience. A formal teaching program with clear objectives and assessment criteria should be developed, and retraining sessions should be conducted on a regular basis and in particular following an episode of peritonitis.

Catheter Placement

Once the decision to initiate PD has been made, it is recommended that the catheter be placed by an experienced surgeon or by an experienced nephrologist if no such professional exists. Different types of pediatric PD catheters have been developed since the original catheter introduced by Tenckhoff [112]. Catheter configurations typically include either a straight or swan-neck tunnel configurations and either a pigtail-curled or straight intra-abdominal portions. The extraperitoneal segment has one or two Dacron cuffs, although for children double-cuff catheters predominate, with a proximal cuff fixed in the preperitoneal area and the distal one in the subcutaneous tissue. Catheters come in 31 cm length for newborns, 38.9 for infants, 42 cm for school-age children, and 62.5 cm for adolescents and young adults. The length of the catheter for each patient can be estimated by the distance between the umbilicus and the symphysis pubis. A double-cuff catheter with a downward or lateral subcutaneous tunnel is recommended for children on maintenance PD by the 2012 ISPD guidelines [127]. Some authors recommend that the catheter be inserted laparoscopically, with the curled portion positioned deep in the pelvis. Omentectomy is critical to prevent obstruction of the side holes of the catheter. Adult surgeons perform an omentopexy, a procedure not recommended in pediatrics to avoid the complication of a potential midgut volvulus. In infants, the exit site should be located above the diaper area. Catheter function and the absence of leaks are often confirmed after the placement with 1–3 passes of 10–20 cc/kg of dialysate by dialysis staff, who ideally should be present at the operating room to flush the PD catheter [124]. A transfer line and a plastic or titanium connector are also part of the connection system to the dialysis system. Administration of a first-generation cephalosporin such as cefazolin just prior to the surgical incision, as described in the ISPD guidelines, is recommended [127]. Vancomycin is an alternative in *Staphylococcus aureus* carriers, as well as in hypersensitivity or resistance to cephalosporins.

Starting PD, Cyclers, and Equipment

Unless there is an urgent need to start dialysis, leakage is a serious complication in PD, especially for infants, and delaying the start of therapy is strongly recommended. If dialysis must be initiated urgently, the recommended initial exchange volumes are 10 ml/kg the first day(s), followed by a slow increase of fill volume depending on the individual clearance needs and risks of leakage (see section “Standardization of Dwell Volume”).

An overview on different modes of PD is given in Fig. 1. Continuous ambulatory peritoneal dialysis (CAPD) is performed using a Y-set of tubing. The Y-set is a simple Y-shaped tube with three branches, with one of them being connected to the catheter through a titanium Luer Lock adaptor. Of the other two branches, one is connected to the fresh dialysate bag and the other to a drainage bag or an open container that collects the drained dialysate. Once the dialysate is drained, “fresh” dialysate is used to flush the tubing before fluid is instilled in the abdomen, the so-called “flush before fill” technique [127]. Automated PD (APD; see Chap. 5) is done overnight using a machine (cycler) that fills the peritoneal cavity with dialysis solution, and after a selected dwell time, the solution is drained, and then, the peritoneal cavity is filled with fresh dialysis solution (nightly intermittent PD, NIPD). When a long daytime dwell is added after the short nocturnal APD dwells, it corresponds to a continuous cycling peritoneal dialysis (CCPD) modality. Cycles performed over a residual volume correspond to tidal PD, a modality which may reduce drain alarms in case of catheter dysfunction. The rationale and mode of adapted APD are described in Chap. 5.7. The dwell time and volume and the number of dwells are prescribed according to the transporter status, intraperitoneal pressure, and mathematical calculations described in Chap. 5.

Various automated PD machines are available in the global market; however, they are all based on the same principle. They allow for infusion volumes ranging from 25 to 3500 ml, depending on the cycler, and are equipped with automated spiking or connecting bags, recognition of barcoded bags, and in-line heating of dialysate.

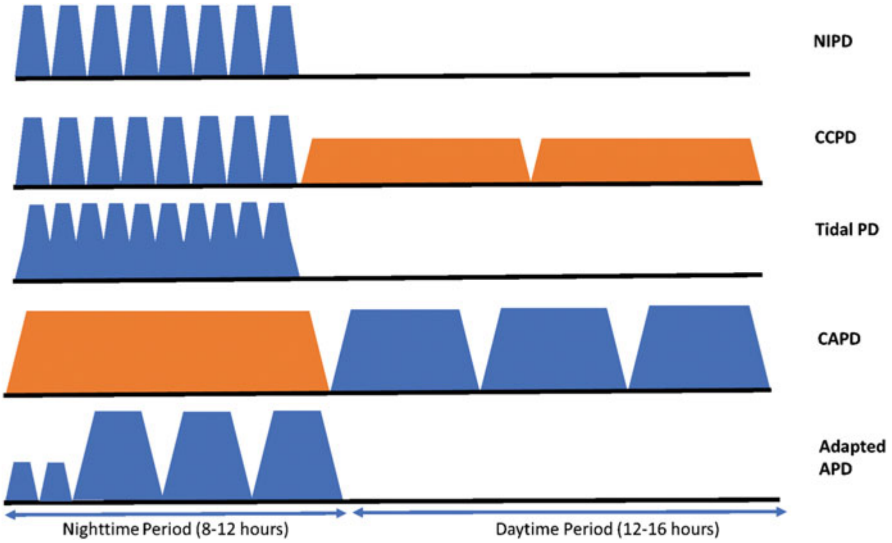

Fig. 1 Schematic illustration of the different modes of PD, based on individual patient's need. To achieve ultrafiltration with tidal PD, intermittent complete drainage may be performed

The most advanced machines have been equipped with remote online monitoring of the procedure (see Chap. 7.2).

Choice of PD Solutions

PD fluids allow for sufficient removal of water and toxins across the peritoneal membrane but due to their highly unphysiological composition (see Tables 1 and 2) result in progressive peritoneal tissue alterations, limiting PD long-term efficiency and sustainability (see Chap. 8). The European Pediatric Dialysis Working Group recommendations therefore emphasize the need for careful PD fluid selection, applying the lowest glucose concentrations and the lowest number of cycles required for adequate ultrafiltration and resulting in the lowest possible cumulative glucose load [100]. In adults, icodextrin solutions significantly increase ultrafiltration and reduce fluid overload. Icodextrin fluids are also well tolerated in children and may therefore be used once daily during the long dwell. To further reduce the dialytic glucose load, amino acid solutions have been developed, but their biocompatibility and nutritive effects in children are uncertain. In the setting of malnutrition, especially in young children, the focus is on optimizing dietary intake, which may require tube feeding.

Multichamber PD bags separate the glucose at a very low pH from the buffer. This largely prevents the formation of toxic glucose degradation products (GDP) during sterilization and storage (Tables 1 and 2). Numerous experimental studies demonstrate untoward effects of GDP. Clinical trials suggest better preservation of peritoneal membrane function and of residual kidney function with low-GDP PD fluids (see Chap. 8). The unphysiological high concentrations of lactate may be circumvented by application of PD solutions containing bicarbonate buffer. A prospective comparison in children with a respective neutral pH, lactate-based solution suggested better preservation of the ultrafiltration capacity with a pure bicarbonate fluid [103]; experimental and ex vivo data suggest reduced peritoneal angiogenesis [32]. Additional benefits may be achieved with bicarbonate buffered fluids in patients with lactate acidosis, as present in case of sepsis and decompensated (inherited) metabolic diseases. The European Pediatric Dialysis Working Group recommends usage of the more expensive, low-GDP fluids whenever possible, and this has

Table 1 Composition of conventional, single-chamber PD solutions

	CAPD 2/3/4 17/18/19	**Dianeal PD 1, PD2#, PD4**	**Gambrosol 10/40**
Sodium (mmol/L)	134	132	132
Chloride (mmol/L)	102.5	102/96/95	96/95

Table 2 Peritoneal equilibration test (PET) results as described by Warady et al. in a cross-sectional study in 95 pediatric patients on long-term PD (mean age 9.9±5.6 years) using 1100 ml/m2 dwell volume [126]. Findings may differ in incident patients, according to ethnicity and age

Patients	Type	4-h D/P creatinine	Characteristics	Measures to consider
10%	High	>0.77	Rapid solute transport absorption of glucose low UF dialytic loss of proteins? Low serum albumin?	Icodextrin modality switch with chronic use of 4% glucose concentrations?
53%	High average	0.65–0.77	Good solute transport moderate UF	APD, shorter and more frequent dwells needed Icodextrin for long dwell
31%	Average	0.51–0.64	Moderate solute transport good UF	APD (CAPD)
6%	Low	<0.51	Slow solute transport very good UF	Long dwells on APD, CAPD

meanwhile been realized in most European and numerous other countries.

Prescription of Peritoneal Dialysis

The child with kidney failure needs adequate replacement of kidney function. Adequate dialysis should be considered as the therapy that allows a nutritional state and growth in normal ranges, as well as a general well-being of the child. Volume overload and uremic status are the main complications that must be resolved, so peritoneal dialysis therapy must focus on obtaining adequate ultrafiltration and clearance of solutes. Each patient's prescription should be individualized according to the water and solute transport capacity of the peritoneal membrane as determined by the peritoneal equilibrium test (PET). Peritoneal dialysis therapy must be prescribed differently for patients who transfer solutes and glucose rapidly, as opposed to slow transporters. The dialysis regime administered should avoid excessive or insufficient solute clearance. The urea clearance applied in a determined time (T) over a solute distribution volume (V), the Kt/V, should therefore be evaluated together with the PET to adjust PD to the requirements of each patient.

Clinical Approach to the Peritoneal Transport

Two concepts have been recognized as important to prescribe dialysis therapy to patient's needs [125]. The first one corresponds to the dialysis dose as measured by urea Kt/V, and the second one evaluates the membrane transport capacity

Table a Composition of multichamber PD solutions

	BicaVera	Balance	Gambrosol trio 10/40	Physioneal 35/40	Extraneal (7.5% icodextrin)	Nutrineal (1.1% AS)

through the peritoneal equilibrium test. Although both concepts involve solute and water transport, urea Kt/V mainly refers to small-solute transport, because depuration mostly depends on the number of cycles and dwell volume. An inadequate PD regime that does not correspond to the PET result will, however, also be reflected by insufficient ultrafiltration and volume overload [40, 88, 125]. The evaluation of the optimal PD dose in clinical practice through tests like the mass transfer-area coefficient (MTAC) and measurement of the hydraulic conductance of the peritoneal membrane results are too complex for clinical routine. The simplicity of urea Kt/V and PET has been the main reason why they have replaced more complex mathematical calculation in clinical guidelines.

The Dialysis Dose, Kt/V Urea

The concepts of **urea Kt/V** and its equivalent, weekly creatinine clearance, were tested decades ago by the CANUSA study [17] and later by the prospective randomized ADEMEX study [82] and others [68]. Although both parameters have been considered to represent dialysis dose, urea removal is more related to the number of cycles and dwell volume, while creatinine clearance is more related to PD duration, because creatinine requires longer membrane transport times.

The Kt/V formula considers three parameters. The first of them is K, clearance (UV/P). K is multiplied by a dialysis time “t” of seven (days) and adjusted to the volume of distribution of urea, total body water “V.” In clinical practice, an easy way to calculate total body water is to multiply 0.6 times body weight (kg), since about 2/3 of the body weight is water. However, a more accurate equation for pediatrics should be used. According to the KDOQI guidelines, TBW should be calculated using the anthropometric formulas of Mellits and Cheek, later revisited by other authors [75]:

$$\mathrm{Kt/Vp\ (peritoneal)} = [\mathrm{Vol\ dial\ (L\ 24\ h)} \times \mathrm{BUN\ dial/BUN\ plasma}] \times 7/\mathrm{TBW}$$

$$\mathrm{Kt/Vr\ (residual)} = (\mathrm{Volume\ of\ urine\ (L\ 24\ h)} \times \mathrm{BUN\ urine/BUN\ plasma}) \times 7/\mathrm{TBW}$$

$$\mathrm{Kt/Vt\ (total)} = \mathrm{Kt/Vp} + \mathrm{Kt/Vr}$$

The CANUSA study evaluated the adequacy of dialysis as measured by the total weekly urea clearance (Kt/V) and total weekly creatinine clearance, finding an 8% decrease in relative risk (RR) of death for each 5 L/weekly of creatinine clearance, the same for each 0.1/week increase in total Kt/V. However, the main effect on patient survival was due to the residual kidney function instead the peritoneal small-solute clearance [6]. In the ADEMEX study, patients treated with a peritoneal urea Kt/V of 1.45–1.74 versus 1.94–2.24 over 2 years mortality was comparable, but RKF significantly impacted patient survival. Based on these and other experiences [80], the 2006 KDOQI guidelines [59] and the Canadian Society of Nephrology [12] recommend that the minimal delivered total dialysis dose (peritoneal and the kidney) should be at least 1.8 and 1.7, respectively, and weekly creatinine clearance >45/1.73 m^2 per week, with special reference to those patients without RKF, defined as a renal Kt/V < 0.1. The KDOQI guideline also suggests that for children, the recommended Kt/V should be at least the adult values. Likewise, the recent ISPD guideline suggests a total Kt/V (peritoneal and the kidney) of at least 1.7 for children [15].

Kt/V has been of help to prescribe the dialysis dose in clinical practice; however, urea is a low-molecular-weight solute, and its depuration is not parallel with other solutes and fluid removal. Therefore, the urea Kt/V should not be used as the only parameter of peritoneal dialysis adequacy [88]. In children, dialysis prescription should be individualized and, in addition to Kt/V assessment of dialysis adequacy, should include the overall clinical status of the patient. In view of the critical importance of controlling serum phosphate with regard to CKD-mineral and bone metabolism (MBD) and its implication in cardiovascular health, the ISPD recently suggested adjusting dialysis dose to optimize serum phosphorus [15].

As mentioned previously, the membrane transfer capacity should be evaluated in each patient through the peritoneal equilibrium test, which represents the capacity of the peritoneal membrane to transfer solutes and water during the dwell.

The Peritoneal Equilibrium Test

In 1987, Twardowski et al. [113] developed a standard test to assess the transport capacity of the peritoneum, the peritoneal equilibrium test (PET). It measures the speed which the concentration of a solute (creatinine) is balanced between the plasma and the dialysis solution by evaluating the ratio of creatinine in dialysate to creatinine in plasma (D/P creatinine) over 4 h. The appearance of creatinine in dialysate is usually measured at hours 0, 2, and 4 along with plasma creatinine at hour 2 (both in mg/dl). Since the initial dialysate creatinine concentration is zero, the creatinine ratio D_0/P_2 will be $= 0$ and will rise in the proportion that this solute is transferred from plasma to dialysate, reaching a maximum theoretical value $D_4/P_2 = 1$ representing a 100% transfer. In cases of low peritoneal transfer rate, the D_4/P_2 creatinine ratio remains low.

Since the velocity of peritoneal glucose uptake is relevant for ultrafiltration capacity, glucose concentration drop in the peritoneal fluid is measured at the same time points as creatinine and expressed as $D_{0\text{–}2\text{-}4}/D_0$. In addition to glucose uptake, it reflects the dilution of the dialysate by ultrafiltration. This includes the movement of free water, a process that predominates in the first hour, and the movement of water and solutes by convection, a process that predominates in the following hours of dialysis. Thus, the initial D_0/D_0 value will always be 1, decreasing later in direct proportion to the factors previously described, deducing that the lower the D_4/D_0 ratio, the greater the transfer capacity of water of the peritoneal membrane and the peritoneal glucose uptake is and vice versa.

From these two parameters, patients are classified into four categories, according to the mean value of the population ± 1 SD. The categories correspond to the following:

- High transporter
  ($D/P_{creatinine} >$ +1 SD of the mean value).
- High average
  ($D/P_{creatinine}$ between the mean and +1 SD of the mean value).

- Low average (D/$P_{creatinine}$ between the mean and −1 SD of the mean value).
- Low transporter (D/$P_{creatinine} < -1$ SD of the mean value).

These categories define the velocity of peritoneal transport, where a high transporter moves solutes and absorbs glucose relatively quickly, in opposite to a low transporter where more time is required to equilibrate plasma and dialysate compartments.

Different authors have reported different cutoff values, since the average of the population studied differs between centers and ethnicities. Cutoff values as obtained in 1996 by Warady et al. in a cross-sectional analysis in children on PD, relative frequency of transporter types, and potential clinical consequences are given in Table 2. In 2007, Warady et al. [123] reported cutoff values for these four categories in a shortened test (short PET) of 2 h. The clinical significance of the transport category is of great importance in clinical practice [125]. Fast transporters generally maintain good solute clearance, but the rapid drop in glucose in the dialysis fluid dissipates the osmotic gradient needed for ultrafiltration, with the risk of volume overload. Short dwell times, as applied in automated peritoneal dialysis (APD, NIPD), are appropriate in this type of patient. Conversely, a low transporter is characterized by a slow transport rate, achieving good ultrafiltration and solute clearance with long dwell times, e.g., 4–6 h as in a CAPD regimen. Short dwell cycles will interrupt ultrafiltration long before the peak of water transport has been reached and result in volume overload and low purification. If cycler PD is used (about hourly nocturnal dwells), long daytime cycles may be required for membranes with low-average transport capacity (CCPD). An inadequate dialysis prescription will lead to insufficient ultrafiltration rates resulting in volume overload and a lower than expected solute clearance (Table 2). Ultrafiltration failure, defined in adults as less than 400 mL in 4-h dwell (3.86% glucose) [46] and less than 150 ml/m^2 during a standard PET in children [124, 125], may ultimately develop with long-term PD and progressive peritoneal transformation (see Chap. 8).

Standardization of PET: Pre-PET Long Dwell

In the original description of the PET, the dwell time of the preceding exchange was approximately 8 h. During this time, the dialysate reaches equilibrium with the plasma. The pre-PET exchange is important because it influences the biochemical condition of the patient at time 0. Lilaj et al. [67] showed that the absence of a pre-PET dialysis cycle significantly altered the D/P values of low-molecular-weight solutes such as urea, creatinine, and proteins. While a long dwell exchange is easily performed in adult CAPD patients, pediatric patients are often on automated peritoneal dialysis, where an 8-h dwell is not suitable. Twardowski et al. [114] demonstrated that a dwell time between 3 and 8 h was acceptable for the preceding exchange dwell, followed by a two (short PET) or four (classic PET) dwell.

PET Protocol Following a 3–8 h dwell, the peritoneal cavity is thoroughly drained upon arrival at the dialysis center. A 2.5% dwell bag with Y-type connection is used to infuse 1100 ml/m^2 (maximum volume 2 liters) in 15 min, with the patient in a supine position and rotating from side to side to promote optimal mixing of the dialysis fluid. Dialysate samples are obtained at 0, 2, and 4 h of the test. To this end, 100–200 ml of dialysate is temporarily extracted (from 1000 to 2000 ml dwells), 5–10 ml samples are collected for creatinine and glucose measurement, and the remaining dialysate is reinfused. A blood sample is obtained after 2 h; complete dialysate drainage is performed after 4 h.

Standardization of Dwell Volume

As discussed previously, the volume of each dwell should meet the requirement of maximizing the peritoneal exchange surface, expressed as the area of pores available for diffusion (Ao/Δx), measured in $cm^2/1.73\ m^2$. Independently of age, the peritoneal membrane surface area is related to the body surface area, while expressed per kg body weight, the peritoneal membrane in infants has twice the surface area compared to adults. A volume calculated in ml/kg results in a smaller dialysate volume for the actual peritoneal exchange area and in faster solute exchange, reflected in the PET by a high D/P creatinine ratio and a low D/D_0 glucose ratio, generating an inaccurate "functional hyperpermeability" [43]. Therefore, the dwell volume should be calculated relative to body surface area.

The dwell volume should consider the resulting intraperitoneal pressure. A high intraperitoneal pressure (IPP) can cause pain and major complications such as hydrothorax, hernias, hydrocele, gastroesophageal reflux, and anorexia and ultimately lead to noncompliance and inadequate PD [41]. High dialysate glucose concentrations, organomegaly, high BMI, constipation, meteorism, abdominal pain, and conventional PD fluids increase intraperitoneal pressure. The majority of patients do not correctly perceive intraperitoneal pressure (IPP) during PD. Standardized measurement of IPP has therefore been suggested, and the details of procedure have been published [41]. The maximum tolerable intraperitoneal volume has been defined in adults as equivalent to an IPP of 18 cm H_2O, above which pain and a decrease in vital respiratory capacity have been reported. An observational study in 61 adult PD patients suggests an increased risk of enteric peritonitis with IPP above 14 cm H_2O [26]. It has therefore been suggested to limit IPP in children on nocturnal PD and above 2 years of age to 14 cm H_2O and to 8–10 cm H_2O in infants, since the latter have a higher risk of hernia and leakage. These IPP values correspond to a dwell volume of about 1200–1400 and 600–800 ml/m^2 BSA, respectively, which should probably not be exceeded. Prospective studies supporting these notions, however, have not yet been performed.

In case urgent PD is needed immediately after PD catheter insertion, initial fill volume should be about 10 ml/kg and can subsequently be increased according to individual needs and risks of leakage (presence of factors increasing intraperitoneal pressure). After that, a volume of 600–800 ml/m^2 in infants and 800–1400 ml/m^2 by dwell in pediatric age may be used as maintenance, always attending tolerance and intraperitoneal pressure.

The ultrafiltration capacity loss over the years leads to chronic volume overload which has been related to the poor cardiovascular outcome in this population. The classic PET is a reliable method to evaluate the peritoneal transport capacity regarding solute and water transport by convection and diffusion but gives no accurate information on ultrafiltration, as shown by the absence of correlation between 2-h creatinine D/P or glucose D/D with solute free water transport (FWT) and ultrafiltration. The PET shows a variability coefficient of $<10\%$ when assessing the transport of small solutes; however, this coefficient increases to 50% when UF is evaluated. The mini PET has therefore been introduced to evaluate the free water transport in dialyzed patients [64].

Free Water Transport: Mini PET

Ultrasmall pores correspond to aquaporin-1 and account for the movement of free water through the peritoneal membrane. In adults and children, during a hypertonic dwell, approximately 40%–50% of UF occurs through the ultrasmall pores as free water without solutes. La Milia et al. [63] proposed a test where a dwell of hypertonic solution (glucose 3.86%) is instilled, allowing measure of the peak of free water transport after 1 h of dwell time based on the osmotic effect of hypertonic dialysate, while sodium transport is minimal due to the low gradient of plasma-dialysate. As detailed previously, sodium sieving, or the decline in sodium in the dwell, is equivalent to the passage of free water from plasma to peritoneum. Only one group thus far has published data on sodium sieving in children [92], even though sodium sieving is clinically relevant. Short dwells with high glucose concentrations as frequently applied in APD remove more water than solutes and may therefore increase total body sodium content and thus thirst, a vicious circle, eventually resulting in high blood pressure.

Optimizing PD Prescription

Volume overload has been repeatedly shown to predict patient outcome. The majority of children on PD are salt and fluid overloaded. An optimized PD regimen requires adequate removal of sodium and water. Based on the fact that free water transport takes place mainly during the first hour of the dialysis cycle while solutes like urea and sodium move slower and mainly through diffusion and convective forces, i.e., relative solute clearance increases with dwell time and dwell volume, whereas net ultrafiltration rates decrease due to the dissipation of the osmotic gradient, Fischbach proposed a modified automated PD regimen combining short, small dwells and high glucose concentration with long and large dwells, the adapted APD [40]. The short, small dwells should favor free water transfer and may result in some hemoconcentration and dilution of the residual dialysate, potentially creating a higher solute gradient for the subsequent large and long dwells. This and the larger dwell volume increase in the peritoneal surface area recruited for exchange should promote solute (sodium) removal (Fig. 1). These assumptions were supported by a randomized, crossed over trial in 19 adult PD patients over two 45-day study periods. The standard PD study period comprised six cycles of 90 min, 2000 ml per cycle, and the adapted one consisted of two initial cycles, 45 min, 1500 ml, followed by three cycles of 3000 ml each, 150 min. Both groups received a similar total volume of 12,000 ml per dialysis session [39]. Both dialysis regimens were well tolerated, but the adapted APD regime resulted in significantly greater clearance of urea, creatinine, and phosphate; higher sodium removal and ultrafiltration; and improved blood pressure. Since then, this approach has been applied in an increasing number of patients, and personal communications are mostly positives, but further systematic studies are lacking, and criteria for individual prescriptions have not been established. Registries suggest a high variability in prescribed adapted APD regimens. The high intraperitoneal pressure created with the large dwells has to be carefully considered (at best measured in each patient), and associated risks of leaks and hernia should be counterbalanced against the potential benefits [44].

Taken together, better control of uremic toxins, especially phosphate, which is closely related to CKD-MBD and CVD, together with optimizing ultrafiltration and sodium removal, which are closely linked to volume overload and cardiovascular disease, is all the result of an appropriate PD prescription. The PD regime should be adjusted periodically in each patient to achieve these results, and surveillance through PET or mini PET, consideration of intraperitoneal pressure, and measurement of Kt/V should be applied routinely to achieve these goals.

The number of cycles overnight may vary according to residual kidney function and the required amount of ultrafiltration and solute removal during nightly intermittent PD (NIPD). One or two additional exchanges may be added during daytime in automated PD (APD), which is then called continuous cycling PD (CCPD). The single long daytime dwell is suited for icodextrin usage. Tidal PD may be useful, e.g., in patients with drainage problems. Cycles are performed over a residual volume; a complete drainage may be performed every 3–5 tidal cycles. Adapted APD uses the same total amount of PD fluid overnight as NIPD but varying dwell time and volume within one session.

Complications of PD

Infectious Complications

PD catheter-related infections include catheter exit site and tunnel infections and peritonitis. Although there is regional variation in infection rates among children on maintenance PD, recent data suggest that in general, rates are decreasing, with a drop in the annualized peritonitis rate among children enrolled in the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) registry from 0.79 episodes per patient year in children initiating PD between 1992 and 1996 to a rate of 0.44 in children initiating PD between 2007 and 2010 [80, 99]. Among children on PD enrolled in the IPPN between 2007 and 2018, the annualized rate of peritonitis was 0.44 [125]. The Standardizing Care to Improve Outcomes in Pediatric End-Stage Kidney Disease (SCOPE) Collaborative, a multicenter quality improvement collaborative in the United States, demonstrated a significant reduction in peritonitis rates by increasing implementation of a standardized PD follow-up care bundle, from a mean monthly rate of 0.63 episodes per patient year at the start of the collaborative to 0.42 episodes per patient years at 3 years post launch [79]. Despite these improvements, infection rates in children on PD remain higher than in adults, and national and international registries continue to reveal that PD catheter-related infections are a frequent and serious complication in children. Peritonitis is the most frequent cause for hospitalization in children on PD, and recurrent peritonitis is a leading contributor to PD technique failure [22, 23, 80, 97]. Infection is a leading cause of death in children on PD [22, 80, 109]. Fortunately, the ISPD has published guidelines specifically for the prevention and treatment of PD catheter-related infections in children [127]. Although early guidelines were largely opinion based, the most recent guidelines were significantly informed by prospective data collected on more than 500 episodes of PD-associated peritonitis in children through the International Pediatric Peritonitis Registry (IPPR), which was conducted with the goal of evaluating the safety and efficacy of the opinion-based ISPD guidelines [37, 99, 127].

Infection Prevention Given the significant morbidity and mortality associated with PD catheter-related infections, infection prevention should be a major focus of the care of the child on PD. Efforts to prevent PD-associated infections begin with PD catheter selection and placement. The types of PD catheter available for children is discussed previously, but in terms of infection prevention, a catheter with two subcutaneous cuffs, rather than one, and a downward or lateral orientation of the catheter as it emerges from the skin, rather than upward, have been associated with lower rates of peritonitis [66, 80, 104, 127, 135]. Infection prevention efforts during catheter placement also include the delivery of intravenous antibiotics prior to the surgical incision [107, 127].

Once the catheter is placed, efforts to optimize healing of the catheter tunnel and exit site, including catheter immobilization and minimizing the frequency of dressing changes, are important to minimize the risk for infection [86]. Delaying use of the PD catheter for dialysis until the exit site is healed will reduce the risk for leaking at the catheter exit site and the associated risk for infection, and data from SCOPE revealed that use of the catheter in the first 14 days after placement was associated with increased risk for early peritonitis [60, 87]. Regular cleansing with a sterile antiseptic solution followed by application of a topical antibiotic is recommended once the exit site is healed [86, 127].

The training of the child and/or caregivers to perform PD in the home should include education about infection prevention, including proper technique for hand hygiene, the aseptic technique for performing the dialysis procedure, and recognition of touch contamination and other breaks in aseptic technique [11, 127]. Education should also include corrective actions for breaks in aseptic technique, which may include treatment with antibiotics and/or transfer set change [127]. Early detection of and treatment for exit site and tunnel infection are important to minimize the risk for subsequent peritonitis [11, 127]. Retraining of caregivers after a peritonitis episode is encouraged [11, 127]. The standardized follow-up care bundle implemented by the SCOPE Collaborative requires that key aspects of hand hygiene, aseptic technique, and exit site care be reviewed with the child/caregiver and that the exit site be scored using an objective scoring tool at each visit in the PD clinic [1, 78, 98]. Compliance with this bundle has been associated with a significant reduction in peritonitis rates among the children on PD enrolled in that collaborative [79]. Additional infection prevention efforts include the provision of prophylactic antimicrobials with invasive procedures and antifungal prophylaxis whenever systemic antibiotics are prescribed [127].

Diagnosis and Treatment of Infection The diagnosis of peritonitis should be considered in any child on PD with abdominal pain and/or cloudy PD effluent, and the diagnosis is confirmed if the PD effluent white blood cell (WBC) count is greater than 100/mm^3 with at least 50% polymorphonuclear neutrophils (PMN) [127]. The PD effluent WBC count should be obtained from a dwell instilled for at least 1–2 h in patients on automated PD. When the effluent cell count is obtained after a shortened dwell, the presence of 50% or more PMN is highly suggestive of peritonitis when the clinical features of peritonitis are present, even if the total WBC count is below 100/mm^3 [127]. Current guidelines recommend that empiric antibiotic treatment be initiated as soon as the diagnosis of peritonitis is considered. Empiric antibiotic coverage should include both gram-positive and gram-negative organisms [127]. In children on PD, gram-positive organisms are the most common causes of peritonitis. Significant regional variability in causative organisms and antibiotic susceptibility have been demonstrated in both IPPR and IPPN, and therefore, local or regional culture results and antibiograms should guide empiric therapy [99, 125]. Intraperitoneal delivery of antibiotics is preferable, typically as continuous therapy with a loading dose which is allowed to dwell for 3–6 h, followed by a lower maintenance dose [127]. The loading and maintenance doses of the most commonly used medications to treat PD-associated peritonitis in children are shown in Table 4 [127].

Current guidelines suggest that monotherapy with cefepime may be considered for empiric treatment for PD-associated peritonitis in children [127]. If cefepime is not available, a first-generation cephalosporin or a glycopeptide (vancomycin or teicoplanin) combined with ceftazidime or an aminoglycoside may be considered [127]. Empiric antibiotics should be modified once culture results are available. Treatment duration should be guided by the causative organism and the clinical course of the child and typically ranges from 14 to 21 days. Fungal prophylaxis is recommended during treatment for bacterial peritonitis [127]. Early identification and aggressive treatment are vital to minimize the risk of peritonitis-related morbidity, including peritoneal membrane failure, and mortality. Peritoneal dialysis catheter removal may be necessary to eliminate infection and minimize injury to the peritoneal membrane, particularly in the setting of refractory bacterial peritonitis, when peritonitis and exit site and/or tunnel infection occur simultaneously with the same organism. Catheter removal is nearly always required in the setting of fungal peritonitis [127].

Purulent drainage at the PD catheter exit site is diagnostic of an infection; however, infection should also be considered when pericatheter swelling, erythema, and/or tenderness is noted, with or without purulent drainage [111, 127]. A PD catheter tunnel infection is diagnosed when erythema, edema, and/or tenderness extends along the catheter's subcutaneous tunnel, with or without the presence of purulent drainage from the exit site [111, 127]. Use of ultrasound may help verify extension of the infection to the tunnel. Exit site and tunnel infections may be caused by many different organisms, including normal skin flora such as corynebacteria [84]. *Staphylococcus aureus* is the most common causative organism, but gram-negative organisms, including *Pseudomonas* species, are increasingly identified in exit site and tunnel infections [84, 85, 108].

Exit site and tunnel infections are typically treated with oral antibiotics, with culture results and antibiotic susceptibilities guiding antibiotic selection [127]. Tunnel infections may require intraperitoneal or intravenous antibiotic therapy if there are signs of severe infection and/or a history of infection with *S. aureus* or *Pseudomonas aeruginosa*. Treatment duration should be guided by evidence of clinical improvement and is continued for at least 7 days after complete resolution of the signs/symptoms that prompted diagnosis [127]. A typical treatment duration is 2 weeks for organisms other than *S. aureus* or *P. aeruginosa*, for which treatment is extended to at least 3 weeks. If complete resolution of the signs/symptoms of infection is not achieved during this time frame or the child on PD develops peritonitis due to the same organism, catheter removal is recommended [127].

Noninfectious Complications

Although infection remains the most common complication of PD in children, noninfectious complications are also a significant problem and can be associated with significant morbidity, including the need to terminate PD [14, 89]. Noninfectious PD complications can be divided into catheter-related complications and complications related to the dialysis procedure [71].

Catheter-Related Complications Catheter-related complications include dialysate leak at the catheter exit site and mechanical catheter dysfunction resulting in inadequate inflow or outflow of dialysate during the dialysis procedure. As mentioned previously, early catheter leak can be seen when the PD catheter is used for dialysis before the catheter tunnel/exit site has healed, and delaying use of the catheter when possible is recommended to minimize this risk [60, 87, 127]. Mechanical dysfunction can occur due to kinking of the catheter, obstruction of the catheter lumen by fibrin or clot, occlusion of the catheter perforations by omentum, and migration of the catheter tip out of the pelvis [71]. Instillation of heparin or tissue plasminogen activator may restore catheter function when obstruction is due to fibrin or clot [135]. Both catheter leak and mechanical dysfunction due to omental occlusion and migration of the catheter may require catheter revision to restore function. Data from the IPDN revealed that among 452 catheter revisions reported to that registry, 60% were performed for mechanical dysfunction and 6% for catheter leak [14]. Constipation may also cause catheter dysfunction by encouraging catheter tip migration as well as external compression of the lumen by bowel [71]. Therefore, children on PD should be regularly monitored for constipation, and bowel regimens to minimize the risk for constipation should be prescribed. Although strictly speaking not a complication, discomfort with inflow and outflow should be anticipated. Discomfort with inflow can be associated with the unphysiological composition of dialysate fluid and "shear" stress, which may abate with time. Outflow discomfort may be related to adherence of the catheter to intraperitoneal structures, especially with small dwell volumes.

Complications Related to the Dialysis Procedure Complications related to the dialysis procedure can be divided into three groups by causation: 1) increased intraperitoneal pressure due to instillation of dialysis fluid into the abdomen, 2) transfer of solute during the dialysis procedure (i.e., metabolic or electrolyte abnormalities), and 3) exposure of the peritoneum to dialysis fluid [71]. The last group is discussed in section "PD Membrane Transformation/EPS" of this chapter.

As mentioned in section "Prescription of Peritoneal Dialysis," adequate exposure of the peritoneal membrane to dialysis fluid is essential for effective solute and water transfer which, in turn, is optimized by increasing the dialysate fill volume. However, increasing fill volume results in increasing intraperitoneal pressure (IPP) [42]. Elevated IPP not only can lead to patient discomfort and intolerance of the dialysis procedure but also may increase the risk of dialysate leaks, even after the catheter exit site has healed [27]. These leaks may present with accumulation of fluid in the subcutaneous tissue, weight gain, and peripheral and/or genital edema. Late leaks may resolve with reduction in fill volume, avoiding a daytime fill, or temporary cessation of PD [27]. Gastroesophageal reflux may also be exacerbated by IPP, and in addition to the typical symptoms associated with reflux, presenting symptoms may include back or abdominal pain [71]. Therapeutic maneuvers include reducing fill volume, particularly during the day. Another complication related to IPP is hernias, which are reported to occur in 6%–8% of adult PD patients [65]. Higher rates are reported in children on PD, ranging from 8% to 57%, and are inversely proportional to age [4, 51, 65]. Areas of anatomic weakness including the umbilicus, linea alba, and inguinal canal, with or without a patent processus vaginalis, and surgical incision sites are at particular risk for hernia development. Given the high prevalence of a patent processus vaginalis in infants and toddlers, it is not surprising that inguinal hernias are common, occurring in over 50% of children starting PD under the age of 2 years in one case series [65]. Accordingly, some surgeons may perform closure of the processus vaginalis at the time of PD catheter insertion in this age group. Efforts to reduce IPP may allow small hernias to be followed, with monitoring for incarceration. However, many hernias in children on PD ultimately require surgical repair.

Another complication related to IPP is hydrothorax, which occurs when fluid enters the pleural space by way of a peritoneal pleural leak, presumably at the site of diaphragmatic defect, typically on the right [24, 110]. Presenting symptoms of hydrothorax include shortness of breath and chest discomfort. Once transudative effusion in the setting of fluid overload is ruled out, the diagnosis is confirmed with measurement of glucose in the fluid obtained by way of thoracocentesis, with an elevated pleural fluid glucose relative to serum glucose verifying peritoneal dialysate as the origin of the fluid. Transient cessation of PD may allow closure of the diaphragmatic defect, and chemical pleurodesis with tetracycline, talc, or autologous blood may be attempted if cessation of PD is not successful [24, 110]. Other therapeutic options include thoracoscopic pleurodesis and thoracoscopic or open diaphragmatic repair [24, 110]. Pericardio-peritoneal leak has also been reported in children on PD and typically presents with tachypnea. As with pleuroperitoneal leak, cessation of PD is usually required [30].

Complications Related to Transfer of Solutes during the Dialysis Procedure The transfer of solutes and water between plasma and dialysate is the therapeutic goal of the PD procedure. However, precise control of solute transfer is not possible, and resultant electrolyte and metabolic derangements should be anticipated and monitored for. Hypokalemia is the most common electrolyte derangement, as standard PD fluid does not contain potassium, and is particularly common in infants and young children who are exclusively fed low-potassium formula or breast milk. In those infants and children, modification of the formula and/or potassium supplementation may be required.

Hypermagnesemia is relatively common in children with chronic kidney disease (CKD) due to reduced clearance of magnesium by the kidney. Magnesium concentrations in commercially available dialysis solutions for PD range from 0.25 to 0.75 mmol/L. Elevated magnesium levels are typically seen with use of solutions containing 0.75 mmol/L magnesium, while use of solutions containing both 0.5 and 0.25 mmol/L magnesium has been associated with hypomagnesemia in adult patients [130, 131]. Inverse correlations between serum magnesium levels and parathyroid hormone (PTH) and fibroblast growth factor 23 have been demonstrated in adults on dialysis, raising concern for increased risk for adynamic bone disease with hypermagnesemia and osteitis fibrosa with hypomagnesemia [54, 81, 130, 131]. Given the lack of data available on magnesium homeostasis in children on PD, current recommendations suggest choosing a solution that allows maintenance of a high normal serum magnesium, i.e., 0.9–1.0 mmol/L, in this population [100].

Hyperglycemia, hyperinsulinemia, and dyslipidemia, known contributors to cardiovascular disease, are unfortunately present in children at the early stages of CKD. Hyperlipidemia was noted in 45% of children enrolled in the Chronic Kidney Disease in Children (CKiD) study, while 4% had hyperglycemia and 9% and 19% had hyperinsulinemia and insulin resistance, respectively [93, 134]. The complex pathophysiological mechanisms contributing to disturbances in glucose and lipid metabolism in CKD are beyond the scope of this chapter; however, it is important to recognize that exposure to glucose-containing dialysis solutions represents a substantial glucose load for children on PD which, in turn, may induce insulin resistance and an atherogenic lipid profile [10, 16, 28]. These findings reinforce recommendations to minimize exposure to glucose by using the lowest dextrose concentration possible, with the addition of icodextrin as required to maintain euvolemia [100]. Given the lack of data on safety and efficacy of pharmacologic agents to treat dyslipidemias in children, Kidney Disease: Improving Global Outcomes (KDIGO) guidelines suggest that statins or statin/ezetimibe combination not be initiated in children less than 18 years of age with CKD, including those treated with chronic dialysis [122]. Therefore, lifestyle modifications including nutrition and dietary counseling are the primary therapeutic intervention for dyslipidemia [122] (Table 3).

Table 3 Dosing recommendations for the treatment of peritonitis

	Continuous therapy[a]		
	Loading dose	Maintenance dose	Intermittent therapy
Aminoglycosides[b]			
Gentamicin	8 mg/L	4 mg/L	
Netilmicin	8 mg/L	4 mg/L	Anuric: 0.6 mg/kg Non-anuric: 0.75 mg/kg
Tobramycin	8 mg/L	4 mg/L	
Amikacin	25 mg/L	12 mg/L	
Cephalosporins			
Cefazolin	500 mg/L	125 mg/L	20 mg/kg
Cefepime	500 mg/L	125 mg/L	15 mg/kg
Cefotaxime	500 mg/L	250 mg/L	30 mg/kg
Ceftazidime	500 mg/L	125 mg/L	20 mg/kg
Glycopeptides[c]			
Vancomycin	1000 mg/L	25 mg/L	30 mg/kg; repeat dosing 15 mg/kg q 3–5 days
Teicoplanin	400 mg/L	20 mg/L	15 mg/kg q 5–7 days
Penicillins[b]			
Ampicillin	–	125 mg/L	–
Quinolones			
Ciprofloxacin	50 mg/L	25 mg/L	–
Others			
Aztreonam	1000 mg/L	250 mg/L	–
Clindamycin	300 mg/L	150 mg/L	–
Imipenem/cilastatin	250 mg/L	50 mg/L	–
Linezolid (oral)	<5 years: 30 mg/kg/day divided TID; 5–11 years: 20 mg/kg/day divided BID; ≥12 years: 600 mg/dose BID		
Metronidazole (oral)	30 mg/kg/day divided TID (max daily dose 1.2 g)		
Rifampin (oral)	10–20 mg/kg/day divided BID (max daily dose 600 mg)		
Antifungals			
Fluconazole	6–12 mg/kg **IP**, **IV,** or **PO** q 24–48 h (max daily dose 400 mg)		
Caspofungin	IV only: Initial dose 70 mg/m^2 on day 1 (max daily dose 70 mg); subsequent dosing 50 mg/m^2 daily (max daily dose 50 mg)		

Used with permission from Warady et al. [127]

Administration should be via intraperitoneal route unless specified otherwise

Intermittent doses should be applied once daily unless specified otherwise

[a] For continuous therapy, the exchange with the loading dose of antibiotics should dwell for 3–6 h, followed by the use of the maintenance dose for all subsequent exchanges

[b] Aminoglycosides and penicillins should not be mixed in dialysis fluid because of the potential for inactivation

[c] Accelerated glycopeptide elimination may occur in patients with residual renal function. If intermittent therapy is used in this setting, the second dose of antibiotic should be time-based on a blood level obtained 2–4 days after the initial dose. Redosing should occur when the blood level is <15 mg/L for vancomycin or 8 mg/L for teicoplanin. Intermittent therapy is not recommended for patients with residual renal function unless serum drug levels can be monitored in a timely manner

PD Membrane Transformation/EPS

Next to achievement of sufficient solute and water removal, preservation of peritoneal membrane function is essential for children requiring long-term PD, in particular in infants yet too small for transplantation and children returning to dialysis after kidney transplant failure. The main risk factors for loss of peritoneal membrane function are the unphysiological composition of PD fluids and severe, persistent, and/or relapsing peritoneal infections.

Single-chamber PD fluids have an acidic pH of 5.5, contain high concentrations of lactate, glucose, and glucose degradation products (GDP), the latter being formed during sterilization and prolonged storage (see Table 1). Studies in adults reveal these fluids result in progressive loss of the mesothelial cell layer, fibrosis and vasculopathy [132], and ultimately in PD failure. The frequency of PD termination due to ultrafiltration failure increases with the time of treatment, in adults from 14% in the first 5 years to 33% thereafter [52]. A key pathophysiological mechanism is transition of mesothelial cells to a mesenchymal phenotype (MMT) and migration of these cells into the submesothelial space, where they secrete numerous proinflammatory and profibrotic cytokines [70].

Double-chamber PD fluids separate glucose at a pH of around 3 from the electrolytes and the buffer, which can either be lactate, bicarbonate, or a mixture of both. GDP formation is largely prevented (see Table 2). Numerous experimental studies demonstrate less toxicity and preserved peritoneal immune response. Peritoneal tissue studies in 172 children, however, demonstrated major membrane transformation with angiogenesis, inflammatory cell invasion, MMT, and respective cytokine induction within few months of PD, and progressive fibrosis with long-term PD [95]. Associated vasculopathy is complement mediated [7]. The largest randomized clinical trial, the balANZ trial, comparing low- and high-GDP fluid PD in 185 patients over 2 years demonstrated lower UF rates and higher solute transport rates during the first year with low-GDP fluids, i.e., a high transporter status, but not thereafter. In patients treated with low-GDP fluids, peritoneal transport rate remained largely stable but increased significantly with high-GDP fluid usage; ultrafiltration rates declined [57, 58]. The trial furthermore suggested a lower incidence and severity of peritonitis with low-GDP exposure; time to anuria was reduced [57, 58]. Other RCTs reconfirmed superior preservation of residual kidney function, altogether reaching adequate power in a respective meta-analysis [53, 58]. Residual kidney function is associated with better survival, lower morbidity, and greater quality of life.

No systematic studies have been performed on the impact of icodextrin-based fluids on peritoneal tissue histology and inflammation. Clinical trials replacing the glucose-based PD solution by icodextrin during the single long dwell, however, demonstrated significantly improved ultrafiltration rates and reduced episodes of fluid overload in adults and a decrease in mortality by 50% compared to PD regimen using glucose-based fluids only. The lower peritoneal glucose absorption with icodextrin-containing PD, however, does not translate in significantly improved systemic glucose homeostasis [49]. Icodextrin may be used especially in children with fluid overload.

Peritonitis episodes may aggravate peritoneal membrane transformation, especially when they are severe and recurrent. In a retrospective study in children, peritonitis caused by *Pseudomonas aeruginosa* or alpha streptococcal organisms was an independent predictor of membrane failure, defined as severe loss of UF capacity [2]. A study comparing 36 children who never had an episode of peritonitis with 57 children with a history of one or more episodes of peritonitis [3] and a longitudinal follow-up study of 26 children suggested higher transport of glucose and creatinine in children with previous peritonitis episodes; all patients were treated with acidic high-GDP fluids. The power of such analyses is limited. Recent studies in children on low-GDP fluids indicate that adequately and successfully treated peritonitis episodes do not have a major impact on peritoneal membrane histology and inflammatory cell and cytokine profile [8]. The GLOBAL Fluid Study suggests an increase in the transporter status with peritonitis episodes together with acidic PD fluids, with high-GDP content, but not when low-GDP fluids are used [34].

In cases where the smoldering inflammatory and transformational process induced by peritonitis episodes and PD fluid toxicity continues, encapsulating peritoneal sclerosis (EPS) eventually develops. EPS is a life-threatening condition reported in 0.7%–3.3% of adult and 1.5%–1.9% of pediatric PD cohorts [105, 118]. Initial clinical symptoms usually comprise abdominal pain and small bowel dysfunction and progress, in its severest form, to complete intestinal obstruction as the bowel becomes trapped in the sclerotic peritoneum. The presence of peritoneal calcifications on abdominal computed tomography scan in association with ultrafiltration failure is highly suggestive of EPS. A European survey in 14 pediatric dialysis centers demonstrated a higher PD vintage of 5.9 (1.6–10.2) years and a higher peritonitis rate than in non-EPS patients. The median interval between UF failure and bowel obstruction was 3 months. In one out of four children, EPS was diagnosed after PD has already been discontinued, i.e., on HD or after renal transplantation. Treatment is debated and usually consists of enterolysis, immunosuppression, or tamoxifen [55]. Mortality was reported to be 35%–69% in adults [5] and 14% in children [105]. Clinical observations suggest a lower incidence of EPS with usage of neutral pH, low-GDP fluids, but respective data from prospective studies are lacking.

Remote Patient Monitoring (RPM)

Home PD requires significant medical and technical knowledge and encumbers families with major responsibility, preventing PD treatment in some families and resulting in early PD technique failures in others. Nonadherence with the prescribed regime is common. In Kansas City, 45% of 51 children exhibited some nonadherence to prescribed PD regimen [25]. One important strategy to improve the quality of care in PD is increasing surveillance and support of the families at home. Cyclers introduced at the beginning of the twenty-first century provide integrated digital card systems for retrospective insight into PD performance, complications, and adherence. The latest generations of PD cycler are now equipped with remote monitoring technology that allows for automated online data transfer of the PD regime, ultrafiltration volumes, and alarms, together with manually entered data such as body weight, blood pressure, and personal comments. This offers real-time remote patient monitoring options by far exceeding surveillance by phone calls, e-mails, and fax [121].

For implementation of RPM, a step wise process is needed (Table 4). Trained persons of the medical team obtain access to their patients' data collected online, which at best should be integrated in existing electronic health records and possibly be amended by videoconferencing functions. Close interaction with trained families is required (Fig. 1); alignment with regional and national laws and regulations has to be verified. Repeated and systematic analysis of the interaction process should improve the RPM process, and impact on current standards of care, e.g., may reduce the frequency of center follow-ups. Other benefits are timely recognition of PD-associated problems, such as catheter dysfunction and peritonitis and inadequate treatment performance, e.g., with regard to PD fluid turnover and ultrafiltration. Immediate adaptation of the treatment can be realized. Due to automated data generation, the burden of collecting and communicating treatment data is reduced. Blood pressure and body weight, however, still require manual entry. By sharing medical responsibility, RPM should reduce the overall burden perceived by the families and increase the families' confidence. The interactive communication should improve individual knowledge and promote the use of PD. Education features may be implemented, too (Fig. 2).

Grade 1A evidence in favor of RPM has been obtained in adult patients with heart failure. In these patients, RPM reduced hospitalizations and mortality, while the impact of mobile phone-based monitoring and videoconferencing remained uncertain [9]. Published RPM experience in pediatric PD is limited. RPM appears useful in

Table 4 Implementation steps for remote patient monitoring (RPM)

Choose device and parameters to monitor; decide on data monitoring and action process
Verify alignment with law and regulations
Train doctors and nurses, followed by patients and carers
Set individual patient alarm margins and alerts
Start RPM
Repeatedly review data sets, alerts, and decisions taken based on RPM
Assess patient perception and adherence to RPM
Reconsider individual and center RPM settings
Systematically evaluate RPM process, and reconsider standards of clinical practice

Center specific data monitoring
Data integrity check
Longitudinal data analysis
Transition planning
Patient flow analysis
Cost analysis
Large scale data analysis

Fig. 2 Schematic illustration of advanced remote patient management with data transfer between the patient and the family at home (green squares) and the dialysis center (purple squares) and respective interactions and possible tools (blue squares)

detecting and solving clinical and technical problems of automated PD, reduces the number of shortened PD treatments [31], and improves fluid status [21]. A prospective study on RPM including videoconferencing in 25 adult PD patients for a total of 200 RPM months and comprising 172 teleconsultations demonstrated reduced emergency room visits and hospitalizations; the associated costs were lower as compared to 32 non-remote managed patients, of whom, however, several had refused RPM [47]. The decline in patient contacts for technical and medical issues during the mean follow-up of one year may reflect RPM-related training effects and improved reassurance of both sides due to the higher degree of surveillance.

Of note, the benefits of monitoring numerous parameters have to be balanced against the risk of data overflow and require standardized RPM procedures within the center and careful communication with the families. Families need to be informed on how often and by whom the data is reviewed. The data surveillance and interventions should be feasible within clinical routine. Overreliance in RPM may reduce situational awareness and personal communication in case of acute problems. The monitoring functions require repeated, patient-specific margin settings and respective alarm signals. Potential technical pitfalls such as false readings must be considered. Thus, critical review of the pursued versus actual therapeutic success is essential at regular intervals during conventional face to face meetings (Table 5). Setting rigorous alarm systems in RPM may result in unnecessary, frequent perturbations of domestic ambiance and possibly in mental and cognitive disconnection with the alarms. Conversely, liberalizing alarm limits may not sufficiently alert families and clinicians to critical scenarios and thus result in potential patient harm. At present, RPM should be considered a beneficial adjunct, but cannot replace face to face communication. Otherwise nonverbal signs may be missed, e.g., in families not coping with the various demands. Likewise, continuous online data assessment may be perceived by some families as inappropriate surveillance and violation of privacy; the families should have the right to discontinue online data transfer times. Overall RPM acceptance, however, is good; the benefits of being supported at home obviously predominate over perceived disadvantages in the majority of families. And reports from pediatric dialysis centers are mostly positive.

Outcomes

Kidney transplantation is the treatment of choice for the vast majority of children with kidney failure. When preemptive transplantation is not possible, dialysis is typically viewed as a bridge or temporary treatment. The primary outcome of interest for children who do require dialysis, therefore, is time to kidney transplantation. Factors that influence access to and timing of kidney transplantation in children are covered is Chap. x.

A PD treatment-related outcome is technique failure or the requirement to discontinue PD due to the loss of a functioning peritoneal membrane. Among children on dialysis enrolled in NAPRTCS, 10% of dialysis terminations were due to inadequate ultrafiltration or solute clearance [80, 129]. In a recent analysis of data from the IPPN, among more than 2400 children on PD with over 3000 patient years of follow-up, 32 experienced technique failure [14]. A history of previous PD catheter revision was associated with a higher risk for PD failure [14].

Although mortality rates for children on dialysis are lower than those seen in adults and recent data suggest improved survival in more recent eras, death rates for children with kidney failure remain unacceptably high [72, 74, 109, 129]. In a recent analysis of data from Europe, the overall mortality rate was 28 deaths per 1000 patient years during the first 5 years of dialysis [22]. Mortality rates are highest in the first year of dialysis and among children under the age of 5 years at dialysis initiation [22]. In this study, children who initiated PD had a lower mortality risk than those on HD, particularly among those older than 5 years of age at dialysis initiation [22]. However, other studies have not demonstrated significant difference in mortality by dialysis modality, and it is recognized that selection bias may be a significant contributor to differences in survival reported in children on PD and HD [119, 129]. Young age has repeatedly been associated with increased risk for mortality among children on PD, with the highest death rates reported in children who initiate dialysis in infancy, although recent analyses suggest improved survival in the infants on PD [18, 80, 94, 109, 116, 129]. The presence of comorbidities and oliguria has both been associated with increased risk of death, particularly in infants on PD [18, 33, 77]. Black race is associated with increased risk for mortality among children on dialysis, which may at least in part be related to difference in access to transplantation [62, 74]. Infection and cardiovascular disease have repeatedly been shown to be the leading cause of death among children on dialysis [22, 74, 119, 129].

Outlook

Neutral pH, low-GDP and icodextrin PD fluids are increasingly used and should further improve PD patient outcome. Novel PD fluid prototypes are being developed. In a recent clinical phase 3 trial, addition of alanylglutamine to neutral pH, low-GDP fluid partially improved small-solute clearance, reduced peritoneal protein loss, improved biomarkers of peritoneal membrane integrity and immune competence, and reduced a marker of systemic inflammation as compared to unsupplemented PD fluid [120]. Current research is focused on novel osmotic compounds with reduced toxicity and lower resorption rates as compared to glucose. Future PD regime should allow for a more refined, individual adaptation of electrolyte and buffer supply to optimize mineral and acid-base balance in order to reduce CKD-MBD and cardiovascular disease. Likewise, advanced, comprehensive, and remote patient monitoring, ideally in a network of digital devices, e.g., including blood pressure and body weight monitoring and videoconferencing, should increase recruitment of PD patients and their families and improve education, quality of life, and patient outcome. On a larger scale, the accumulating treatment data should provide significant information on technical shortcomings, PD efficacy, and complications and may allow for refined individual prognostic modelling. The human element of medicine, on the other hand, must not be lost of sight when implementing the digitally enhanced care pathways. Critical and comprehensive evaluation is mandatory in order to improve our ultimate targets, as well- defined by the Song-PD initiative [69].

Abstract

Conventional hemodialysis (HD) is a widely used kidney replacement therapy for children with end-stage kidney disease. HD is based on diffusive transport of solutes across a semipermeable membrane and is effective in removing small uremic retention solutes such as urea, correcting electrolyte abnormalities and restoring fluid balance. The addition of convective therapies with hemodiafiltration (HDF) allows the removal of larger uremic retention solutes, such as β_2-microglobulin and inflammatory cytokines. Extended hours of hemodialysis, best achieved through home hemodialysis programs, achieves optimal clearances without the hemodynamic strain of conventional HD. Despite technical advances, children on dialysis continue to experience high rates of morbidity and mortality compared to the general pediatric population.

In this chapter we discuss the principles, technique and practical aspects of performing conventional HD and intensified dialysis techniques, including HDF and home hemodialysis, in children, and relevant pediatric and adult studies to support these practices. We outline commonly encountered complications of HD and strategies for their prevention and treatment. Vascular access, often called the “Achilles’ heel” of dialysis, is discussed at length, comparing the relative merits of central venous lines and arteriovenous fistulas. Finally, we suggest future directions for children treated with HD including the benefits of intensified hemodialysis options.

Keywords

Hemodialysis (HD) · Hemodiafiltration (HDF) · Home hemodialysis · Diffusion · Convection · Arteriovenous fistula (AVF) · Central venous line (CVL) · Dialyzer · Intradialytic hypotension

Introduction

Hemodialysis (HD) is the most efficient dialysis modality. Advances in technology have brought hemodialysis from the rotating drum system first devised by Kolff [1] to a sophisticated, highly automated method applicable to patients from infancy to adulthood, delivered in multiple settings including patients' homes. With this advancement comes complexity requiring knowledge and thoughtful collaboration between physicians and dialysis staff to assure safe and effective patient care. Multiple components – vascular access, dialyzer, dialysis fluid proportioning system, ultrafiltration controller, and safety mechanisms – must work in harmony to provide a successful hemodialysis session. The dialysis team must leverage their expertise and clinical judgment to develop an appropriate hemodialysis prescription and deliver the therapy to the patient while monitoring closely for possible complications.

Epidemiology of Pediatric Hemodialysis

The United States Renal Data System (USRDS) 2019 Annual Data Report [2] demonstrates that 51.3% of incident patients with end-stage kidney disease (ESKD) in the USA aged 21 years or younger (677 of 1319) begin their ESKD care receiving HD, with the remainder split between peritoneal dialysis (27.8%) and kidney transplant (20.8%). By comparison, prevalence data within the same cohort show 73.3% undergoing kidney transplantation with only 16.6% receiving HD, which comprised 61.8% of children receiving maintenance dialysis. Distributions vary further depending on the age of the pediatric patient, with HD use being less common in younger patients. In the United Kingdom, the UK Renal Registry 21st Annual Report [3] indicates 966 prevalent patients age 18 years or younger at the end of 2017 requiring kidney replacement therapy (KRT); 217 of these patients were on maintenance dialysis with 120 (55.3%) on HD. The European Society for Pediatric Nephrology – European Renal Association Registry reports that in children aged <15 years from 37 European countries approximately 5.5 per million age-related population start KRT annually. Unlike trends in the USA, the majority of incident pediatric ESKD patients in Europe started KRT with peritoneal dialysis (47%), followed by hemodialysis (33%), and preemptive transplantation (20%) [4].

Dialysis Initiation

The optimal time to start chronic dialysis remains controversial. A recent Kidney Disease Improving Global Outcomes (KDIGO) guideline suggests that, in the absence of symptoms, there is no specific estimated glomerular filtration rate (eGFR) for initiation of dialysis and current data do not support preemptive dialysis initiation [5]. The IDEAL study, the first randomized controlled trial on dialysis initiation either in early or late CKD stage 5 (CKD5) in adults, showed that early initiation of dialysis (at an eGFR of 10–14 ml/min/1.73 m^2) in patients with CKD5 was not associated with an improvement in survival or clinical outcomes compared to an elective delayed start (an eGFR of 5–7 ml/min/1.73 m^2) [6]. IDEAL showed that with careful clinical management, dialysis may be delayed until either the eGFR drops below 7 ml/min/1.73 m^2 or traditional clinical indicators for the initiation of dialysis are present [6]. Although the Kidney Disease Outcomes Quality Initiative (KDOQI) guideline published in 2006 suggested that dialysis should be considered when eGFR falls to <14 ml/min/1.73 m^2 and recommended when eGFR falls further to <8 ml/min/1.73 m^2 [7], three recent national and international guideline bodies clearly indicate that in the absence of symptoms there is no benefit from starting dialysis early [5, 8, 9]. The UK National Institute for Health and Care Excellence (NICE) [8], the Canadian Society of Nephrology [9], and the 2015 KDOQI guideline for HD adequacy [10] have all suggested that dialysis should be initiated at an eGFR of 5 to 7 ml/min/1.73 m^2 if there are no uncontrollable uremic symptoms, biochemical abnormalities, or fluid overload.

In children, three studies from the USRDS and the European Society of Pediatric Nephrology (ESPN) registry [11–13] also conclude that there is no benefit from starting dialysis early. Taken together, these registries have examined the association between eGFR at initiation of chronic dialysis and clinical outcomes in over 21,000 children. Of almost 10,000 incident dialysis patients aged 1 to 17 years in the USRDS registry (1995–2016), a higher eGFR at the start of dialysis was associated with an increased risk of death. Mortality risk increased in those starting dialysis with eGFRs <5 and ≥ 12 ml/min/1.73 m^2, with a greater risk in patients 6 years and older [12]. A further study from the USRDS assessed eGFR in the range of 5–12 ml/min/1.73 m^2, in which most CKD5 patients start dialysis; the mortality risk was 36% higher for those with eGFR >10 ml/min/1.73 m^2 compared with those with lower eGFR at dialysis initiation [13]. An observational, retrospective cohort study of nearly 3000 patients aged <18 years from the ESPN registry examined two populations of children who started dialysis with an eGFR above or below 8 ml/min/1.73 m^2 [11] and found that mortality did not differ between the two groups. However, the lack of an evidence base has led to variations in practice both between and within countries: the median eGFR at dialysis start is currently 8.2 and 7.8 mL/min/1.73 m^2 for children in Europe and the United States, respectively [4, 14], with a trend towards an earlier start of dialysis reported in the USRDS registry [13].

While formal estimates of GFR are neither practical nor useful in CKD5, KDIGO suggests that risk equations can be helpful in predicting a time frame for when KRT may be needed. In pediatric practice, two formulae have been developed to prognosticate progression to ESKD. Using the Chronic Kidney Disease in Children (CKiD) study cohort, the Kidney Failure Risk Equation uses age, sex, eGFR, and albumin/creatinine ratio (a 4-variable equation) to estimate the rate of progression to dialysis or transplant [15]. A second equation using a multinational collaborative study in 1169 children (ages 1–16 years with an eGFR of 15–90 ml/min/1.73 m^2 and a median follow-up of 3.8 years) is based on eGFR, proteinuria and the CKD diagnosis (glomerular vs. nonglomerular) to determine CKD progression [16].

Dialysis Modality Selection

Dialysis modalities include in-center conventional HD or hemodiafiltration (HDF), home HD, and continuous ambulatory or automated peritoneal dialysis (PD). All extracorporeal dialysis modalities (HD, HDF, and home HD) are together referred to as HD in this chapter. The principles and practice of PD is described at length in ▶ Chap. 75, "Peritoneal Dialysis." There are no robust data to suggest that one modality is superior to another and both HD and PD have relative advantages and disadvantages.

The only absolute contraindication for maintenance HD is the absence of suitable vascular access. All other health conditions are relative contraindications, and therefore, the selection of dialysis modality needs to reflect informed patient choice with decision support appropriate to the health care system. Patients and caregivers need to be informed of the challenges, considerations, and trade-offs of the different dialysis modalities so that modality selection can be tailored to their health and social circumstances [17]. Although preserving residual kidney function is important, it should not be the sole consideration in selecting the initial dialysis modality.

Physiology of Hemodialysis

All dialysis modalities operate under physical principles related to the movement of molecules in aqueous solutions across semi-permeable membranes. Understanding these basic principles allows full recognition of the processes engaged in dialysis therapies and gives the operator more control over the prescription and the procedure. These processes include diffusion, convection, and ultrafiltration. Molecules in the bloodstream will also adsorb to the dialyzer and blood tubing, which represents an additional, though ill-defined and uncontrolled, mechanism of molecular removal.

(i) ***Diffusion*** describes the movement of molecules from an area of higher concentration to an area of lower concentration. In an aqueous system with two chambers separated by a semipermeable membrane (Fig. 1a), dissolved molecules will tend to move by random motion across the membrane down their concentration gradient. Net movement ceases when the particle concentration is equal across both compartments. Smaller molecules diffuse more quickly than larger molecules; this relates to the relative amount of energy required to cause molecular movement. The membrane will restrict movement of any particle that is larger than the membrane pore diameter despite a favorable concentration gradient. Small molecules bound to larger molecules such as proteins behave as if they were larger and may not diffuse; only the free fraction would be able to cross the membrane. Diffusion is bi-directional; molecules may move in either direction until achieving equilibrium. Dialysis therapies that employ a dialysis fluid, such as HD, operate by diffusion. Molecules in the blood will diffuse across the dialyzer membrane into the dialysis fluid, becoming the spent waste dialysate, while those substances within the dialysis fluid that are at higher concentration than the blood have the potential to diffuse across the membrane into the patient.

(ii) C***onvection*** describes molecular movement across a semipermeable membrane under the force of pressure; the net pressure vector pushes water, with dissolved solutes, across the membrane (Fig. 1b). As opposed to diffusion, in which smaller molecules move with greater ease, small or larger molecules will move across the membrane at an equal rate since movement is not dependent on energizing the particles; all solutes up to the cut-off size of the membrane pores pass equally. The net pressure vector arises from a combination of positive pressure on the source side of the system and negative pressure on the destination side, leading to a unidirectional molecular movement.

(iii) ***Ultrafiltration*** describes the movement of the water itself. In hemodialysis, blood flow through the dialyzer generates a positive hydrostatic pressure; the hemodialysis system governs the net pressure vector by adjusting

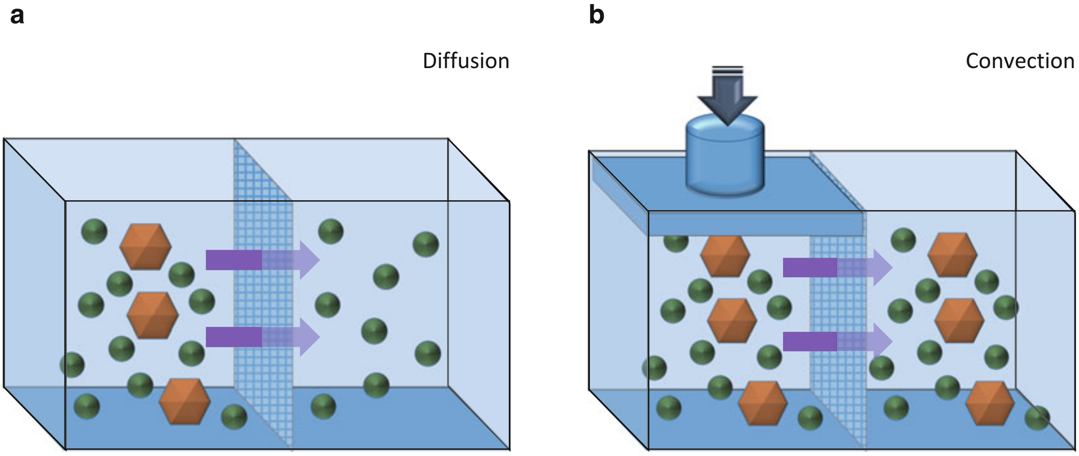

Fig. 1 The principles of diffusion (**a**) and convection (**b**) across a semi-permeable membrane

the hydrostatic transmembrane pressure applied to the dialyzer. Ultrafiltration and convection always occur simultaneously.

Technical Aspects of Hemodialysis

Figure 2 provides a schematic of the hemodialysis system, illustrating the blood and dialysate circuits.

The Blood Circuit

The blood circuit carries the patient's blood to the dialyzer and then returns the blood to the patient via the vascular access. Analogous to arterial and venous systems in relation to the heart, the arterial limb of the blood circuit moves blood away from the patient towards the dialyzer and the venous limb carries blood from the dialyzer to the patient. Monitoring systems within the arterial and venous limbs measure dynamic pressure throughout the dialysis session, providing an assessment of appropriate flow. Abnormal pressures generate alarms that prompt the operator to check for blood flow obstruction or disconnection. The venous limb will also have an air detector to monitor for entrained air within the blood circuit. When triggered, the air detector stops the blood pump and clamps the venous limb to prevent air entry to the patient.

Tubing for the blood circuit must be compatible with the chosen HD device; many companies offer HD systems that require purchase of their proprietary tubing sets while others may permit generic tubing. When prescribing the HD session, one must consider the total extracorporeal blood volume within the tubing set and the hemodialyzer relative to the patient's circulating blood volume. Most manufacturers offer tubing sets in several sizes to

accommodate smaller pediatric patients; pediatric hemodialysis teams may need to review their options when considering purchase of HD systems to ensure that they can safely accommodate all patients in their pediatric group.

The HD system draws blood from the vascular access via a rotating roller pump at the arterial limb of the blood circuit. Blood pump rotation generates flow rates ranging from a minimum of 10–30 ml/min to a maximum up to 500 ml/min; this is an important parameter chosen by the operator to prescribe the dose of HD. The roller pump must maintain appropriate occlusive pressure on the portion of the tubing within the pump housing device to produce consistent forward flow and to avoid complications including hemolysis or foaming of blood within the circuit. Pressure variances and inappropriate flow may lead to audible “thump” or “knock” with each revolution of the blood pump or trigger an alarm that stops the blood pump for safety.

Hemodialyzers

Modern hemodialyzers are of hollow-fiber design comprised of multiple capillary tubes manufactured from semipermeable material through which blood flows, embedded within a cylindrical plastic cartridge in which dialysate bathes the exterior of the artificial capillaries (Fig. 3). Each capillary tube represents a semipermeable membrane across which diffusion, convection, and ultrafiltration may occur. Early HD membranes were made of cellulosic material but had a risk of causing allergic reactions. As a result, hemodialyzer composition evolved through modified cellulosic materials to fully artificial (plastic) biocompatible membranes. Manufacturers develop and market numerous variations of dialyzer membranes, which may differ in porosity, thickness, surface charge, and relative biocompatibility. Clinicians who prescribe hemodialysis should be knowledgeable regarding these differences to make appropriate choices for patients and avoid complications [18].

Hollow fiber dialyzers come in various sizes to permit safe and effective HD for patients of all ages and sizes (Table 1). Smaller dialyzers, appropriate for younger children, will have a lower priming volume, the amount of blood necessary to fill the dialyzer during the session. Larger dialyzers will have larger priming volumes. Similarly, the surface area available for dialysis will vary with the size of the dialyzer; smaller dialyzers will have lower surface areas compared to larger dialyzers. These factors prove important when developing the prescription for a patient as membrane surface area has an impact on HD efficiency and priming volume of the dialyzer is a component of total extracorporeal blood volume.

All dialyzers undergo sterilization by the manufacturer before sale. Some sterilizing methods

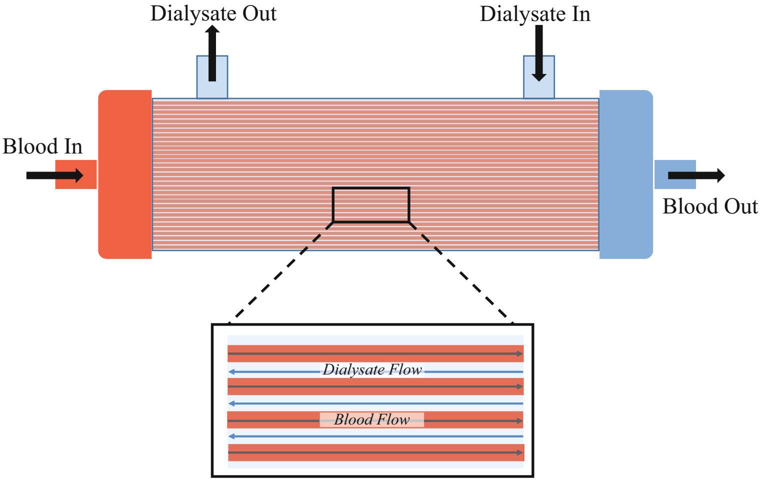

Fig. 3 Hemodialyzer schematic showing counter-current flow of blood and dialysate

Table 1 Dialyzer characteristics, options, and considerations for pediatric hemodialysis

Dialyzer characteristic	Range of options	Considerations
Surface area	0.2 m^2–2.5 m^2	Larger surface gives greater capacity for clearance and ultrafiltration but requires high blood flow to achieve these advantages
Priming volume	18 ml–140 ml	Consider along with tubing set volume to determine maximum safe extracorporeal volume, especially for smaller patients
Membrane material	Cellulosic, modified cellulose, artificial	Cellulosic membranes considered less bio-compatible and may lead to more allergic-type reactions; greater bio-compatibility with progression to modified cellulose and then to artificial (plastic) membranes
Sterilization	Ethylene oxide (ETO), gamma irradiation, steam, electron beam	Allergic reactions associated with ETO; fewer reactions with gamma and steam
Flux	Low flux vs. high flux	Higher flux dialyzers have higher permeability (e.g., larger pores), permitting higher rates of middle molecule clearance and higher UF rate at a given prescription
Clearance (typically described as K_D for urea (ml/min) at Q_B 200 ml/min)	K_0A urea 170 ml/min – 1700 ml/min	Varies with surface area, flux, membrane material
Ultrafiltration capability (K_{UF} ml/h/mmHg)	K_{UF} 7 ml/h/mmHg – 111 ml/h/mmHg	Varies with surface area, flux, membrane material

may leave residual chemicals within the dialyzer that require rinsing and may put the patient at risk for reactions at the time of the procedure. This has been well described with ethylene oxide (ETO), a formerly ubiquitous method for dialyzer sterilization. Many manufacturers now sterilize by steam or gamma irradiation (Table 1) to avoid this concern.

Within the HD circuit, the dialyzer serves as the "artificial kidney." Two dialyzer characteristics are important for treatment effectiveness: the porosity of the membrane and the surface area available for diffusion. These together define the permeability surface area product (K_0A). The K_0A, expressed in ml/min, describes the maximum diffusion capacity of a dialyzer for a given solute. A larger dialyzer with greater surface area will have a higher K_0A than would a smaller dialyzer made from the same membrane material. Two dialyzers of identical size and surface area may not share the same K_0A due to differences in membrane material and relative permeability. The clearance (K_D) of a dialyzer, also with units of ml/min, describes the ability of the dialyzer to remove a given molecule from the blood in a unit time under the conditions of a specific dialysis prescription. K_D is a function of the K_0A but also varies with the blood flow rate (Q_B) and dialysis fluid flow rate (Q_D).

The ultrafiltration coefficient (K_{UF}) is an analogous concept. Expressed with units of ml/h/mmHg, the K_{UF} describes the ability of the dialyzer to ultrafilter a volume of water per unit of time at a given transmembrane pressure. Dialyzers with higher K_{UF} will efficiently ultrafilter at lower transmembrane pressures; a dialyzer with a lower K_{UF} will not be able to increase ultrafiltration above its limit despite the application of higher transmembrane pressures. One must consider K_0A, K_D, and K_{UF} when developing the dialysis prescription for an individual patient (see below).

The Dialysis Fluid Circuit

The dialysis fluid is the aqueous solution into which substances from the blood will diffuse.

The dialysis fluid circuit includes components to generate and test the fluid before it enters the dialyzer and a system to deliver the dialysate to the dialyzer. Historically, it was necessary to prepare the total volume of dialysate for HD sessions ahead of time. On-line preparation of dialysis fluid, using a proportioning system to combine dialysis-grade water and electrolyte concentrates to generate just-in-time dialysis fluid during the HD session, largely has replaced the original "batch" systems [19].

To ensure safety, one must minimize the presence of molecules within the dialysis fluid that may pose a risk to the patient. Municipal water may have high mineral content, particulate matter, or additives such as chlorine, which may make the water acceptable for ingestion but can harm a dialysis patient should they diffuse into the bloodstream. The water treatment system, therefore, is an essential component of any HD unit [20]. Combining particle filtration, water softeners, activated charcoal perfusion and reverse osmosis membranes, current water treatment systems make tap water suitable for dialysis. Governmental agencies around the world list specific guidelines for dialysis water, specifying expected levels of purity, and monitoring regimens to which dialysis units must adhere.

The concentration of electrolytes in dialysis fluid should approximate those of serum, with adjustments to correct the imbalances related to kidney failure. Concentrates of electrolytes, available as liquids or bulk powders, when mixed with the water, make dialysis fluid. For bicarbonate-based dialysis fluid, separation of dialysis fluid concentrates into two components prevents precipitation and simplifies storage. The acid component, often denoted as "A" and color-coded red, contains sodium, calcium, magnesium, potassium, glucose, and chloride, combined with an organic acid. One may choose from a variety of "A" component formulations to yield a final dialysis fluid with the desired electrolyte content; in particular, there are options for potassium and calcium concentration depending on the clinical situation. The base component, marked as "B" and color-coded blue, contains the bicarbonate.

The proportioning system within the dialysis machine draws up "A" component, "B" component, and water to blend the three streams into dialysis fluid. The system tests the dialysis fluid by continuously measuring its conductivity to assure the electrolyte content is accurate before delivery to the dialyzer. If conductivity falls outside of the expected range, the system diverts the dialysis fluid away from the dialyzer and the machine alarms to notify the operator. The mixed dialysis fluid enters the dialyzer cartridge and bathes the blood-filled capillary fibers, providing a destination for diffusion. To optimize diffusion efficiency, blood and dialysis fluid flow in opposite directions within the dialyzer (counter-current flow). Settings for dialysis fluid flow rate may be limited depending on the brand of dialysis machine; common options are a minimum rate of 300 ml/min and maximum rate of 800 ml/min.

Ultrafiltration Control

Earlier generations of dialysis machines required manual calculation and adjustment of the transmembrane pressure to achieve ultrafiltration (UF) goals. This process was fraught with risk to the patient due to inaccurate UF. Modern dialysis machines include automated UF control systems that precisely monitor transmembrane pressure and the rate of water transit across the dialyzer to assure accuracy of fluid removal. Every dialysis system has an inherent level of UF inaccuracy which is quantified in the dialysis system specifications. As a result, the prescribed UF can differ from the actual UF, necessitating careful monitoring and assessment of the patient's volume status throughout the dialysis treatment, especially for smaller children.

Vascular Access

A well-functioning vascular access is crucial to the success of dialysis. There are three types of vascular access for chronic HD: central venous lines (CVLs) which are tunneled cuffed catheters placed in a central vein, arteriovenous fistulas

(AVFs), and arteriovenous grafts (AVGs) using prosthetic or biological material. The ideal vascular access is one that provides adequate blood flow for solute clearance and has a low risk of infection or causing damage to the vasculature. There is robust evidence to recommend AVFs over CVLs in adult patients, and pediatric studies suggest similar outcomes with improved dialysis clearance, fewer infections, fewer hospitalizations, and fewer access changes [21–24]. Guidelines on vascular access for chronic HD recommend the use of AVFs over CVLs where feasible [25, 26]. However, AVFs may not be suitable in the very small child or those with an anticipated short dialysis course before transplantation or transition to PD, so the Fistula First program [21] may not be appropriate for all children.

Prevalence of Different Access Types Used Globally

Although AVFs are recommended as the preferred vascular access for the majority of children, CVLs remain the most frequently used access type in all pediatric age groups [14, 26–28], possibly because of the perceived convenience of CVLs. The International Pediatric Hemodialysis Network (IPHN) reported that in over 550 children from 27 countries only 26% of all access types were AVFs, and CVLs were the predominant access type in 72% [27]; this trend was also noted in children older than 10 years. Data from the European Pediatric Dialysis Working Group demonstrate a different proportion with 38% of all access types being AVFs [29]. Across all registries, AVGs are used in <2% of children and usually as a last resort when other options have been exhausted [27, 29]. Recent guidelines from the European Society of Pediatric Nephrology Dialysis Working Group (EPDWG) suggest that children requiring chronic HD should start with a functioning AVF where appropriate but recognize that not every child is a suitable candidate for AVF formation [26]. A dedicated vascular access clinic that includes dialysis nurses, play therapists, and psychologists [30] is a useful “hub” to promote patient education [23, 31] regarding preferential access options.

CVL Types and Sites of Placement

One must consider and carefully choose the type and size of catheter, catheter site, and technique for insertion for each patient. The internal jugular vein is the preferred site. CVLs in the femoral vein are associated with a higher risk of infection and thrombosis [32] so should be avoided except in emergencies or where all other access has failed. Subclavian catheters are associated with a high risk of postoperative stenosis [33], limiting options for future vascular access. Although there are no comparative studies in children, a fluoroscopic or ultrasound-guided technique for CVL insertion may be considered to prevent mechanical complications at the time of CVL insertion. The IPHN report suggests that vascular access dysfunction was more common when the CVL was placed in the femoral (56%) or subclavian vein (35%) as compared to the internal jugular vein (21%) [27].

AVF Formation

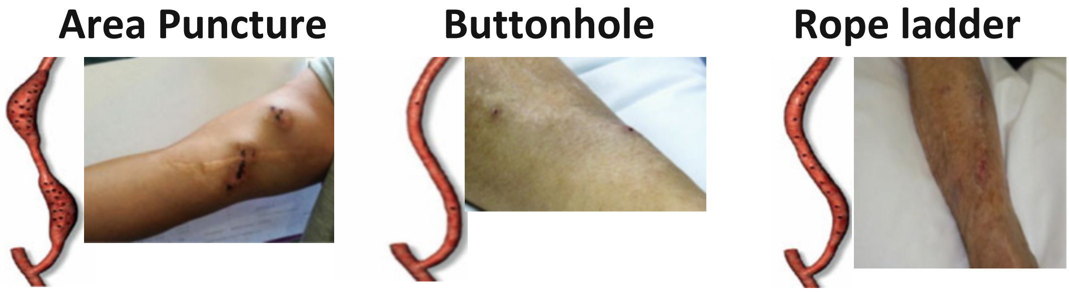
An AVF is created by surgically connecting an artery to a vein, which transmits higher pressure to the vein, causing it to expand, after which large enough needles may be inserted to provide the high blood flows required for dialysis [34]. The AVF may be created at the wrist (radiocephalic) or the elbow (brachiocephalic) or by basilic vein transposition to create a brachiobasilic fistula. It is preferable to create the first AVF distally at the wrist to preserve more proximal vessels for future use. The nondominant arm is preferred for AVF formation as this will allow for self-needling of the AVF, easy use of the dominant arm during dialysis, and limit any potential neurovascular complications of surgery.

While some groups are able to create AVFs in very young children using microsurgery [34], larger vessels are usually associated with higher rates of AVF maturation and successful use. Vein mapping prior to AVF surgery can direct the surgery to an anatomical site that has the best chance of success. In general, the intraluminal diameter of the vein should be at least 3 mm. In small patients, a two-stage basilic vein transposition may be preferable; the anastomosis is created in the first stage and about 4–6 weeks later the arterialized vein is brought to the surface to make access easier [34]. There are no randomized studies comparing different sites of AVF formation in adults or children but registry data suggests that radio-cephalic AVFs have excellent primary and secondary patency rates of 78–85% and 94%, respectively, comparable to those for brachiocephalic AVFs [35]. The success of AVF depends on adequate outflow distal to the anastomosis, or else high venous pressures may result. Thus, a child who has had previous central lines may need upper limb venography to confirm patency of the central vessels [36]. Ultrasound examination of the proximal vessels can be misleading and should not be relied upon because collaterals may be mistaken for patent upper limb vessels, and veins cannot easily be seen under the clavicle.

AVF Cannulation

Two prospective studies in children have reported an average maturation time of 8–10 weeks for the majority of AVFs [31, 37] with no significant difference between AVFs at different anatomical sites [27]. One study suggests that the timing of first AVF needling should be delayed to at least 45 days after AVF creation, as this has been associated with improved primary and secondary patency rates compared to earlier AVF cannulation [38]. The first AVF cannulation usually starts with a single needle of a smaller size, and in some centers with ultrasound guidance, gradually building up to larger needle sizes and two needles.

An AVF can be cannulated by the rope ladder, buttonhole, or area puncture technique (Fig. 4). While the expertise and preference of the person cannulating an AVF is a critical factor, systematic reviews of trials in adult HD patients do not show



Area Puncture

Technique:
- Single cannulation site in one small area
- Both cannulation sites on the same segment but do not meet
- Sharp needles

Benefits:
- Patient choice – needle phobia
- Small AVF – space
- Reduced infiltrations

Disadvantage
- Bleeding, aneurysms, AVF thrombus
- Stenosis
- Body image

Buttonhole

Technique:
- Same hole in the skin, same place in the vein; same person needling to establish a track
- Pick scabs; start with sharp needles
- Blunt needles once track has been established
- 3 – 4 buttonholes along vessel

Benefits:
- Less pain with needle insertion
- Reduced bleeding time post needle removal
- Fewer missed cannulations
- Decreased risk of aneurysm formation
- Promotes self cannulation

Disadvantage:
- Scab picking; increased infection risk
- Easy to mistake for area puncture

Rope ladder

Technique:
- Over at least 8cm segment
- Each site 0.5-1cm above previous
- Sharp needles
- Cannulation -zip / central or traditional / side to side, moving up the vein

Benefits:
- Reduced risk of stenosis or aneurysm formation
- Lower infection risk

Disadvantage:
- Needs long segment of fistula vein
- Harder needle insertion
- Increased risk of infiltration
- Still requires planning

Fig. 4 A schematic diagram showing the different techniques of arteriovenous fistula cannulation, and the relative advantages and disadvantages of each technique

a clear benefit of buttonhole cannulation in terms of patient survival, access survival, quality of life, needling pain, infection, bleeding during or after dialysis, and aneurysm formation [39, 40]. A recent cross-sectional survey of cannulation practices suggests that the area puncture technique was associated with a higher rate of access failure than the rope ladder or buttonhole techniques, and is no longer recommended [41]. Buttonhole cannulation carries a higher risk of access infection [42] and must be avoided in children with frequent skin infections.

Outcomes of AVFs and CVLs

The IPHN data suggest that AVFs have better event free survival probability and higher primary and secondary patency rates up to four years after creation compared to CVLs [27]. Having a CVL increased the need for new access at a different site by two-fold [27]. In addition, multiple retrospective studies in children have shown that CVLs present a significantly higher infection rate, risk of access related sepsis, and higher rates of hospitalization than AVFs [22, 23, 28, 37, 43].

Prescribing Hemodialysis and Special Considerations for Children

HD prescription for children requires careful review and a patient-specific approach. Standardized prescriptions may lead to inappropriate doses of dialysis, putting the patient at risk for complications. The following section of this chapter describes the components of a pediatric dialysis prescription and methods for its development; prescription and monitoring of dialysis dose is described in ▶ Chap. 78, "Adequacy of Dialysis."

Blood flow rate through the HD circuit (Q_B) is a major determinant of dialysis solute clearance; the vascular access determines the maximum Q_B that is achievable. Since the resistance to flow through a tube (e.g., blood through a blood vessel or a CVL) is inversely proportional to the fourth power of the radius, larger central venous catheters and AVFs will tend to allow higher Q_B and permit more efficient hemodialysis. Conversely, smaller vascular access (e.g., in infants and younger children) limits the maximum Q_B achievable for treatment. To prevent saturation of the dialysate and consequent reduction of diffusion capacity, the dialysis fluid flow rate (Q_D) is required to be 1.5–2 times that of Q_B.

When selecting a dialyzer for chronic HD, consider the dialysis goals for the session and the volume of the dialyzer. The dialyzer forms part of the extracorporeal circuit volume; perfusing a HD circuit with a blood volume more than 10% of the patient's intravascular volume increases the risk for hypotension and shock. As a general rule, the dialyzer membrane surface area should be approximately equal to the patient's body surface area. Practitioners should also consider the dialyzer membrane material and sterilization method, given risks for reactions during the session.

With the choice of Q_B, Q_D, and dialyzer, one may then determine the predicted clearance (K_D) for the session. Since urea is a small molecule that distributes in the total body water and is easy to measure in the patient's blood, it is a convenient marker for small molecule clearance during dialysis. Dialyzer manufacturers publish urea clearance (K_D(urea)) values for their dialyzers but may only report those clearances associated with higher Q_B as performed for adults; if a child's vascular access cannot generate Q_B within the listed range, K_D(urea) must be estimated and is usually approximates the Q_B itself.

With a value for K_D(urea) determined, all necessary data are present to calculate the time for dialysis using the mass transfer equation. The mass transfer equation describes the diffusion of a given molecule from the blood into the dialysis fluid. The mass transfer equation has the following format:

$$C_t/C_0 = e^{-Kt/V}$$

The term "e" is the base of the natural logarithm function. The variables in the mass transfer equation are:

C_t = the concentration in the blood of the molecule in question at time "t."
C_0 = the concentration in the blood of the molecule in question at time zero (start of HD).
K = the dialytic clearance of the molecule in question.
t = the time of the dialysis procedure in minutes,
V = the volume of distribution of the molecule in question in milliliters.

If the molecule in question is urea, one may use the K_D(urea) and the other known variables to solve the equation for the length of the dialysis session (t) to achieve the desired urea clearance. The mass transfer equation permits one to model the change in blood concentration of a substance under the effects of the dialysis procedure. This allows control over the prescription and the ability to achieve the goals for a HD session.

Consider the following clinical example using the mass transfer equation to determine a first prescription for HD:

> A patient weighing 50 kg with previously undiscovered kidney disease presents with a blood urea nitrogen (BUN) concentration of 100 mg/dl. The patient will require HD; the first HD session often targets lower urea reduction to prevent the complications of dialysis dysequilibrium (see below). A 30% reduction in BUN (goal 70 mg/dl) would be reasonable. The acutely placed CVL is likely to deliver Q_B of 200 ml/min; data table for the selected dialyzer reports K_D(urea) of 185 ml/min at Q_B 200 ml/min. Total body water can be estimated as 60% of the body weight (30 kg or 30,000 ml). Using these data, re-arrange the mass transfer equation to solve for time of the HD session (t):
>
> $t\ (\text{minutes}) = -\ln (C_t/C_0) \times (V/K)$
> $t\ (\text{minutes}) = -\ln (70/100) \times (30{,}000/185)$
> $t\ (\text{minutes}) = -\ln (0.7) \times 162.2$
> $t\ (\text{minutes}) = -(-0.357) \times 162.2$
> $t\ (\text{minutes}) = 0.357 \times 162.2$
> $t\ (\text{minutes}) = 58$

While many patients will dialyze using a standard dialysis fluid, some patients require adjustment to the more commonly used blend (Table 2). Choosing different options for the "A" component can yield varied concentrations for potassium in the final dialysis fluid. A common default concentration for potassium in the dialysis fluid is 2 mmol/L, chosen to generate an outward diffusion gradient and negative potassium balance for a patient who lacks kidney function. The potassium bath concentration choice requires caution and careful thought; an overly rapid decrease of potassium when dialyzing against a very low concentration may cause cardiac arrhythmias. For this reason, the use of dialysis fluids without any potassium (zero K baths) should be strictly prohibited. For individuals who undergo dialysis daily and have poor dietary intake, dialyzing against a 2 mmol/L potassium bath may lead to total-body potassium depletion; such a patient may benefit from dialyzing with a 3 mmol/L potassium bath. One may take a similar approach when choosing from different options for the calcium concentration, with normal values between 1.25 and 1.75 mmol/L (2.5–3.5 meq/L).

Table 2 Common dialysate composition for hemodialysis

Component	Dialysis fluid concentration	
	US units	SI units
Sodium	137–144 mEq/L	137–144 mmol/L
Potassium	0–4 mEq/L	0–4 mmol/L
Chloride	98–112 mEq/L	98–112 mmol/L
Bicarbonate	27–40 mEq/L	27–40 mmol/L
Calcium	5–7 mEq/L	1.25–1.75 mmol/L
Magnesium	0.61–2.43 mEq/L	0.25–1 mmol/L
Glucose	0–198 mg/dl	0–11

One may adjust other components of the dialysis fluid concentration including the sodium and bicarbonate levels. However, the method involves manipulating the blend of "A" component, "B" component and water in the proportioning system. Consequently, these adjustments lead to changes in the concentrations of all components of the dialysis fluid.

Consider the following clinical example to illustrate choice of dialysate:

> The patient in the example above, presenting for first dialysis session with previously undiscovered kidney failure, has other biochemical abnormalities in addition to initial BUN of 100 mg/dL. Blood testing prior to first dialysis session includes the following results:

Patient values	US units	SI units
Sodium	137 meq/L	137 mmol/L
Potassium	5.8 meq/L	5.8 mmol/L
Chloride	102 meq/L	102 mmol/L
Total CO2	16 meq/L	16 mmol/L
Calcium (total)	6.8 mg/dL	1.7 mmol/L
Phosphorus	10.1 mg/dL	3.3 mmol/L
Albumin	2.9 g/dL	29 g/L

Of note, the patient presents with above-normal potassium, low total CO2 indicative of metabolic acidosis, low calcium, and high phosphorus. A reasonable choice for dialysis fluid concentrations may be as follows:

Dialysis fluid	US units	SI units
Sodium	140 meq/L	140 mmol/L
Potassium	2 meq/L	2 mmol/L
Bicarbonate	30 meq/L	30 mmol/L
Calcium (total)	3.5 meq/L	1.75 mmol/L

Note that the potassium concentration of the dialysis fluid is lower than that of the patient, permitting diffusion and removal, but the gradient is not so large as to potentially increase the risk for arrhythmia. The bicarbonate concentration is higher than that of the patient, which will permit some correction of the metabolic acidosis, but is somewhat lower than that used in more routine sessions to avoid an overly rapid correction which could exacerbate risk for arrhythmia due to intracellular potassium shift. The patient's hypocalcemia prompts use of a higher dialysis fluid calcium concentration to support correction and again reduce risk of arrhythmia. Daily HD sessions for 3–5 consecutive days may be needed to correct the imbalances slowly and safely, after which one may consider transition to a more routine dialysis fluid concentration such as the following:

Dialysate fluid	US units	SI units
Sodium	140 meq/L	140 mmol/L
Potassium	2 meq/L	2 mmol/L
Bicarbonate	35 meq/L	35 mmol/L
Calcium (total)	2.5 meq/L	1.25 mmol/L

Note that the potassium concentration in the dialysis fluid is most often 2 meq/L (2 mmol/L) for thrice-weekly HD to address potassium accumulation in the interdialytic period. Adjustments to the dialysis fluid concentration may be required for patients on different HD schedules, as one may see with home HD (see below).

The acidifying agent in the "A" component is most commonly acetic acid. Citric acid may serve as an alternative [44, 45]. If used, the citrate in the dialysis fluid may provide some local anticoagulation at the membrane, improving dialyzer efficiency. Some users report reduction of or complete elimination of the need for heparin anticoagulation during dialysis sessions using citrate based dialysis fluid [46].

The dialysis machine controls the dialysis fluid temperature, which can vary 1–2 degrees Celsius around the standard temperature of 37 °C. Colder dialysis fluid may limit hypotension and hypoxia during the dialysis session [47–49] but too low a temperature causes patients to feel cold, which they tolerate poorly.

Many patients with renal dysfunction undergoing HD will have volume excess due to oliguria. During the HD session, one must choose a goal volume of fluid to remove from the patient via UF. Modern automated UF control systems permit the operator to program a goal fluid target and for the dialysis machine to govern the transmembrane pressure, yielding the target volume of ultrafiltrate in the prescribed time. Clinical factors related to the patient and technical aspects of the therapy deserve consideration when planning the UF goals, as outlined next.

While excess fluid within the patient may distribute to multiple body compartments, the HD procedure only has access to the vascular compartment. Even in an otherwise healthy patient without systemic illness or cardiac dysfunction, overly rapid removal of fluid from the vascular compartment by UF may lead to symptomatic hypotension while not removing the excess fluid that remains within the interstitial space. One may mitigate the risk for hypotension through slower rate of UF. This may lead to insufficient fluid removal in the prescribed session time or may necessitate extending the length of the procedure to achieve the goal with a slower UF rate. It is easier to achieve UF goals for patients who have a smaller volume of fluid to remove and who have normal vascular tone; UF is more difficult to manage for patients who have significant volume overload (an interdialytic weight gain of >8%) or have poor vascular status, as may be seen in critically ill patients with sepsis. Thus, those undergoing HD in the setting of systemic diseases including sepsis or multiorgan dysfunction may benefit from either daily HD sessions with lower per-session UF targets to maintain fluid balance or, if available, extended or continuous forms of kidney replacement therapy that will distribute the UF goal throughout the day (see ▶ Chap. 67, "Evaluation and Management of Acute Kidney Injury in Children"). Those patients with cardiac dysfunction are also at increased risk for complications with rapid ultrafiltration as they may not be able to compensate for intravascular volume removal with increased cardiac output, and their risk for myocardial hypoperfusion will be increased (see below). Younger children may be particularly prone to symptomatic hypotension due to their relatively small intravascular volume; careful bedside monitoring by experienced dialysis staff, sometimes with the assistance of technology such as noninvasive blood volume monitors, can help to assure safer and more comfortable HD sessions while achieving appropriate ultrafiltration goals [50, 51]. For maintenance HD sessions, many programs will choose to limit, by policy, maximum UF goal per session (e.g., no greater than 5–8% of the patient's current target "dry" weight) or UF rate (e.g., no greater than 10–13 ml/kg/h) to remain in a "safe zone" that allows appropriate compensation between intravascular and extravascular fluid compartments. As noted above, this is easier to achieve with limited intradialytic fluid gain, longer HD sessions, or daily HD schedules; in conventional thrice-weekly HD, it may be challenging to remain within these parameters and also achieve appropriate volume control [52].

Anticoagulation for Hemodialysis

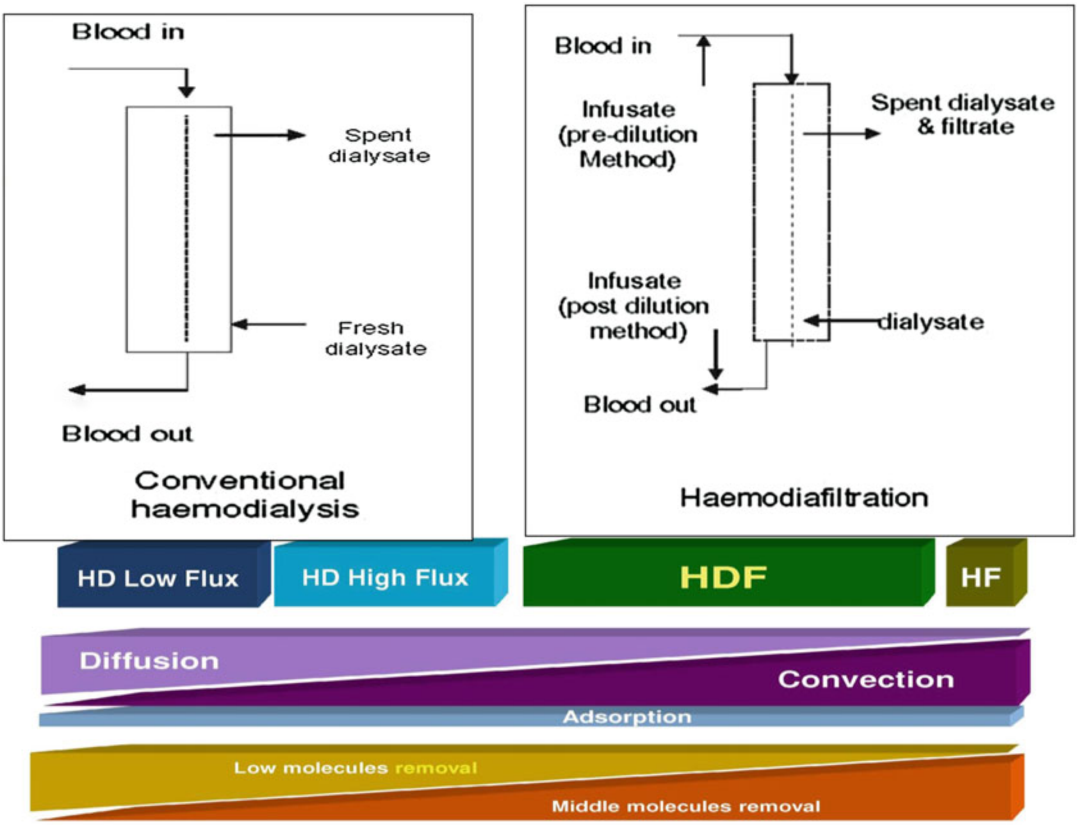
Membrane and tubing surfaces in the blood circuit activate the coagulation cascade and cause clotting. Most dialysis circuits will require anticoagulation to perform HD successfully. Systemic unfractionated heparin has been the longstanding anticoagulant for HD. Most circuits will receive an initial bolus of heparin at the start of the HD procedure, followed by a continuous infusion at a lower rate to maintain anticoagulation throughout the session. Alternatives methods include bolus at session start without infusion or infusion only without starting bolus; variations may depend on local practice or on patient-specific issues. While effective, heparin has the disadvantage of being a systemic anticoagulant that may predispose the patient to bleeding; this is less commonly a problem with intermittent HD sessions since the exposure time is four hours or less. Heparin-induced thrombocytopenia is possible but relatively uncommon in the pediatric population; when it occurs, one must suspend heparin use. Alternatives to systemic heparin include regional citrate anticoagulation or use of citrate-containing dialysate which provides local anticoagulation at the dialyzer membrane [45, 46]. If anticoagulant-free dialysis is required, intermittent flushing of the dialyzer with saline may be performed, but this may lead to a high sodium and volume load to the patient.

Hemodiafiltration

Standard HD clears uremic toxins primarily through diffusion, with clearance being inversely proportional to the molecular size, protein binding, and tissue distribution of the toxin. Recognizing the importance of larger uremic toxins, it is evident that there is a need for alternative therapies that provide better removal of those solutes, leading to the development of a combined convective and diffusive therapy, hemodiafiltration (HDF). Figure 5 shows a schematic presentation of HD and HDF circuits.

Definition of HDF

The European Dialysis (EUDIAL) working group has defined HDF as a blood purification therapy that combines diffusive and convective solute removal by ultrafiltration of 20% or more of the blood volume processed through a high-flux dialyzer and maintenance of fluid balance by sterile replacement fluid infused directly into the patient's blood [53]. In on-line HDF, large volumes of sterile replacement fluid are obtained by



Blood in
Spent dialysate
Fresh dialysate
Blood out
Conventional haemodialysis
Blood in
Infusate (pre-dilution Method)
Spent dialysate & filtrate
Infusate (post dilution method)
dialysate
Blood out
Haemodiafiltration
HD Low Flux
HD High Flux
HDF
HF
Diffusion
Convection
Adsorption
Low molecules removal
Middle molecules removal

Fig. 5 A schematic presentation of hemodialysis (HD) and hemodiafiltration (HDF) circuits and their mechanisms of clearance by diffusion alone (HD) vs a combination of diffusion and convection (HDF)

on-line filtration of standard dialysate though a series of bacteria- and endotoxin-retaining filters [54]. A high convective volume is a fundamental requirement for HDF. The convective volume is the sum of the net UF volume (i.e., the amount of fluid removed during a dialysis session based on the interdialytic weight gain) and the amount of substitution fluid (i.e., the sterile replacement fluid given as replenishment for the removal of extra fluid during HDF).

Convective clearance optimizes the removal of middle (up to 300–500 Dalton [Da] molecular weight) and larger (greater than 15–50 kDa) molecules. Randomized controlled trials [55–58] suggest that any improved survival associated with HDF occurs when the convective volume exceeds 20 liters/session. Modern HDF machines can achieve convective volumes of 30–35% and should be aimed for in order to obtain optimal clearance.

Modes of HDF

The location within the dialysis circuit where one infuses replacement fluid defines the different modalities of HDF (Fig. 5):

(i) ***Postdilution HDF*** **–** The replacement fluid is infused downstream of the dialyzer, usually into the venous bubble-trap. A potential disadvantage is that hemoconcentration at high UF rates can result in the deposition of plasma proteins on the membrane surface, clogging the membrane pores, and occluding the blood channels of the dialyzer. These effects can raise transmembrane pressure (TMP), causing alarms, reducing clearance, and possibly resulting in clotting of the extracorporeal circuit [53].

Hemoconcentration generally limits the convective volume achieved to 20–25% of blood flow rate in postdilution HDF. The ultrafiltration rate is controlled in proportion to the actual blood flow rate or guided by TMP. A filtration fraction up to 35% of the blood flow rate is possible using systems designed to optimize filtration rate, based on automatic adjustment of TMP according to UF flow rate measurements [59].

(ii) ***Predilution HDF*** **–** The replacement fluid is infused upstream of the dialyzer. Ultrafiltration rates up to 100% of blood flow rate are used. Predilution reduces the efficiency of both the diffusive and convective components of solute removal by reducing solute concentrations in the blood compartment, and for equivalent clearance, the convective volume needs to be 2 to 3 times greater for predilution compared to postdilution HDF [60].

(iii) ***Mid-dilution HDF*** **–** The replacement fluid is infused part-way down the blood pathway using specially designed dialyzers – the first part of the blood circuit is operated in post-dilution mode and the second part in pre-dilution mode [61]. Very large filter sizes, up to 1.9 $\mathbf{m^2}$ are required, and hence, this technique is not suitable for children.

(iv) ***Mixed dilution HDF*** **–** The replacement fluid is infused both upstream and downstream of the dialyzer in varying ratios. As with mid-dilution HDF, the need for large filter sizes precludes its use in children.

Postdilution is the most efficient mode of HDF for clearing middle and large molecular weight substances and is the most commonly used HDF technique in adults and children, but in patients with low blood-flow rates, predilution HDF may be preferred.

Requirements for HDF

Essential requirements for performing HDF include:

(i) ***"Ultrapure" water for replacement of convective volume.*** The sterile, nonpyrogenic fluid used to maintain fluid balance, referred to as replacement fluid or substitution fluid, is generated on-line by filtering dialysis fluid through bacteria- and endotoxin-retentive filters to prepare a sterile and pyrogen-free solution that is immediately infused into the patient (therefore also called on-line HDF). The International Organization for Standardization (ISO) has defined ultrapure dialysate as containing <0.1 colony-forming unit/ml and < 0.03 endotoxin unit/ml. Bacteria- and endotoxin-retentive filters installed on the inlet dialysis fluid circuit are key components of the on-line HDF safety system. As large volumes of fluid are removed from, and added to, blood during HDF, strict safety standards and regulatory oversight are required.

(ii) ***High flux membranes.*** Only highly permeable membranes, defined as membranes with an ultrafiltration coefficient (K_{UF}) greater than 20 mL/h/mmHg transmembrane pressure and a sieving coefficient (S) for β_2-microglobulin (β2-m) of greater than 0.6 [53, 62], are suitable for HDF. The K_{UF} defines the hydraulic permeability of a membrane and a high-flux membrane allows a larger and predefined convective flow as required for HDF. As with conventional HD, the dialyzer surface area must be equal to (or slightly higher) than the body surface area, keeping in mind that the internal volume of the dialyzer and blood lines is less than 10ml/kg body weight. For HDF, a biocompatible dialyzer must be selected; biocompatibility is assessed by complement activation, thrombogenicity, contact activation, and cytokine generation [63]. European recommendations state that ultra-pure dialysate must be used with synthetic high-flux membranes [53], both in HDF and HD modalities.

(iii) ***Dialysis machines with accurate ultrafiltration control.*** Many of the new dialysis machines allow for both HD and HDF and are suitable for children above 10–17 kg body weight depending on the machine specifications.

The Concept of Back-Filtration

Since blood and dialysis fluid pass through the filter in counter-current directions, and the hydrostatic pressure of both fluids decreases as they pass through the filter, the resulting TMP may become negative at the venous side, causing an influx of dialysis fluid into the blood compartment of the dialyzer; this is called back-filtration. This phenomenon is a routine occurrence during high-flux HD [64], but not in low-flux HD. The high internal UF rate may increase convective transport of middle molecules [65]. In adults the convective volume achieved by back-filtration is no more than 1–10 L per session depending on the dialyzer type and can vary throughout the dialysis session depending on TMP. Since the convective volume achieved by back-filtration is low and unreliable, it should not be considered a form of HDF. Importantly, given the phenomenon of back-filtration, it has been suggested that dialysis fluid used for high-flux HD should also be sterile and pyrogen-free.

Potential Advantages of HDF over Conventional HD

HDF is thought to be superior to conventional HD through the following mechanisms:

(i) **Improved clearance of toxins across a wide molecular weight range**. HDF clears 70–80% of β2M compared to HD [66] and increase removal of inflammatory cytokines with reduction in inflammation and oxidative stress [67].

(ii) **Improved hemodynamic stability.** HDF permits increased net UF and improves intradialytic hemodynamic stability [68], leading to less intradialytic hypotension [69], reduced incidence of strokes [56], and faster recovery time postdialysis [70].

(iii) **Biocompatibility and reduced inflammation.** The use of "ultrapure" dialysate and increased removal of inflammatory cytokines reduces inflammation and oxidative stress [67].

HDF Studies in Adults

In adults on dialysis, the Estudio de Supervivencia de Hemodiafiltración On-line (ESHOL), one of the largest RCTs comparing HDF vs high-flux HD in adults, has shown that patients on high volume HDF have a survival benefit compared to those on high-flux HD [56]. Pooled data [58] from the RCTs has indicated a critical dose-response relationship between the magnitude of the convective volume and survival, with a goal of at least 23L per session. A Cochrane review suggests that there is no clear benefit of HDF over HD but this review combined outcomes of hemofiltration and HDF studies as convective therapies and did not assess outcomes based on convective volumes [71]. Improved cardiovascular outcomes in adults on HDF are, at least in part, explained by improved hemodynamic stability, leading to less intradialytic hypotension and faster recovery time after dialysis [56, 57, 69].

HDF Studies in Children

HDF is increasingly used in children in Europe but until recently there have been few data on outcomes. Fischbach and colleagues showed improved nutrition and growth [72], reduced inflammation [73], regression of left ventricular hypertrophy [73, 74], improved anemia control [73], and reduced postdialysis recovery time [72] in a small number of children undergoing daily HDF. HDF may have an anabolic effect associated with the greater removal of uremic toxins such as inflammatory cytokines and hormones that regulate appetite and growth, as well as superior clearance of accumulated endogenous somatomedin and gonadotropin inhibitors, improving target tissue sensitivity to growth hormone [75]. In a cross-over trial when HD patients were switched to HDF keeping all other dialysis related parameters constant, an improvement in inflammation, antioxidant capacity, and endothelial risk profile was achieved within 3 months [67].

A multicenter observational study tested the hypothesis that HDF improves the cardiovascular risk profile, growth and nutritional status, and health-related quality of life outcomes in children compared to conventional HD – the HDF, Hearts, and Height (3H) Study [70, 76]. Children receiving HDF had improved blood pressure and hemodynamic stability, reduced inflammatory markers, and lower β2-m compared to children on HD [70]. There was a very high prevalence of subclinical cardiovascular disease in children on dialysis, but an attenuated progression of carotid intima-media thickness increase was noted in children receiving HDF compared to those receiving conventional HD [70]. The annualized change in vascular measures correlated with improved BP control and clearances on HDF. Importantly, children treated with HDF reported a reduction in the frequency and/or severity of headaches, dizziness, and cramps on dialysis, as well as a reduction in the postdialysis recovery time, leading to an improvement in school attendance as well as physical activity [70]. Lower interdialytic weight gain on HDF, implying lower ultrafiltration rates per session and greater hemodynamic stability, was strongly associated with fewer symptoms. There was no reduction in serum albumin levels with HDF and no difference in the rate of change of residual renal function [70] in children on either dialysis modality, implying that HDF is a safe treatment.

Optimization of the Convective Volume

Every effort must be made to optimize the patient's convective volume to achieve the best outcomes from HDF. Convective volume may be improved by:

(i) ***Optimal vascular access.*** Both CVLs and AVFs can be used for HDF provided a good extracorporeal blood flow is achieved. The 3H study showed that it is possible to safely achieve high convection volumes (median 13.4 L/m^2) in children [76], which is comparable to the 23 L/1.73 m^2 session that proved beneficial in the adult studies [58], with no difference in the blood flow achieved through either type of access [70, 76]. With the exception of initial cannulation, one must use the largest AVF needle size suitable for the access type.

(ii) ***Optimal blood flow rates.*** The maximal blood flow rate that can be safely used will result in the optimal convective volume. The true blood flow rate may often be somewhat lower than the set value and the higher the blood pump speed, the wider the difference [77]. As blood flow rate increases, recirculation may occur, especially if there is inadequate arterial inflow or obstruction in the venous outflow; regular monitoring is required to avoid access recirculation.

(iii) ***Anticoagulation.*** Postdilution HDF may induce considerable hemoconcentration, so adequate anticoagulation is required. Unfractionated heparins have a molecular weight in the range of 2–20 kDa, so large convective volumes are likely to alter their pharmacokinetics [78], and higher doses than used with both low-flux and high-flux HD may be required [79, 80].

Home Hemodialysis

Home hemodialysis (HHD) was introduced in the early 1960s by groups in Boston, London UK, Seattle, and Hokkaidō, but was rapidly replaced in the 1970s and 1980s with the rise in hospital affiliated HD facilities. In the 1990s, as the demand for dialysis began to exceed the capacity within dialysis facilities, the interest in HHD returned. As HHD numbers started to increase, a new narrative began to unfold on the potential health and psychosocial benefits of HHD and practices started to expand worldwide.

HHD Definitions and Prescriptions

Home HD transfers dialysis treatments from hospital settings to patients' homes. One of the key characteristics of all HHD practices is augmented HD prescriptions, owing to a higher frequency of dialysis sessions per week or longer dialysis treatments. Typically, HHD regimens are subdivided according to their duration (treatment hours per session), frequency (alternate days or 4–7 times per week), and timing (daytime or overnight). One of the key drivers for families to transition to HHD is the flexibility to deliver the treatments around their own schedules.

HHD is prescribed as a weekly dose (standard Kt/V), individualized in partnership with the patient and their caregivers. Changes to the prescription are common and encouraged if an improvement in patient outcomes and/or quality of life is possible, balancing any decision against the potential burden of delivering care, as highlighted in Table 3.

Patient Selection Criteria

The referral for HHD is often initiated for medical, social, or educational reasons, or simply families exercising their right of choice. Failed home PD does not preclude the possibility of HHD. Criteria to consider include:

- A commitment to consistently delivering the dialysis schedule at home both by the patient and their caregivers.
- The patient weight cut-off criteria are determined by the choice of home dialysis system and equate to the combined volume of the extracorporeal circuit and dialyzer.
- Well-functioning vascular access.
- Absence of psychosocial concerns that cannot be adequately managed.
- Suitable accommodations that allow for the dialysis equipment and 2–4 weeks supply of dialysis consumables; adequate hygiene levels not to increase the patient's risk of infection.
- Ability to modify the water source if a reverse osmosis dialysis system is selected.
- The family does not live in an area with frequent and prolonged electricity supply disruptions or they have available an emergency source of power.
- Patient is medically stable even in the presence of possible multiorgan diseases.

Requirements for a HHD Program

Infrastructure Establishing a HHD program requires a central focus on safety. The service delivery model can vary considerably and is largely influenced by:

- Available resources and expertise
- Fully independent pediatric program or need to partner with a neighboring pediatric or adult program
- Dialysis regimens: Exclusively daytime schedules or include nocturnal treatments
- Dialysis system – consider dialysis consumables, deliveries, home modifications that may be required, service and maintenance for the dialysis machine and dialysis fluid system
- Training within the dialysis program or in a dedicated HHD training facility

Staffing and Remote Support It is crucial to recruit a multidisciplinary team to support HHD families, with a HD nurse, dialysis biomechanical engineer, nephrologist, dietitian, pharmacist, and social worker at minimum. It is essential to have a clear remote support structure for the family, so they understand how to access immediate help at any time. Patients should return to clinic regularly, every 4–8 weeks, and between clinics have regular contact with the HHD nurse specialist.

Training and Education Ideally it is advisable to train two people from the outset and involve patients to promote a degree of independence. All families should be offered repeated opportunities to enhance their knowledge and skills once home or following an adverse event or change in dialysis access such as switching from central line to AVF. Training can take place in the HD unit or within a separate training facility.

Table 3 Essential considerations when selecting the most appropriate pediatric HHD prescription

Prescription	Session duration [h]	Sessions per week	Patient or family considerations	Prescription considerations
Short daily	2–3	6–7	Helpful for working/busy parents with a limited window for dialyzing Higher frequency best for children with high UF requirements such as enterally fed infants or children poorly adherent to fluid restrictions.	Most expensive option due to higher dialysis consumables cost Dialysis and blood flow rates are typically unchanged from in-center prescriptions 2 h prescriptions not suitable for infants as the extracorporeal circuit volume becomes a significant additional UF burden on top of the interdialytic weight gain Dietary and fluid restrictions often unchanged
Extended	4.5–6	Alternate days at minimum to 7 days per week maximum	Alternate-day therapy offers greatest respite time for the caregiver Teenagers become increasingly frustrated sacrificing their evenings to HD Longer duration best for children with intradialytic symptoms and cardiac instability	Dialysate and blood flow rates typically 15%–30% lower than in-center prescription May require higher dialysate calcium requirement, especially infants and teenagers with higher growth rates Often allows liberalization of dietary and fluid restrictions Improved BP control, lower antihypertensive requirement
Nocturnal	7–12	Alternate days at minimum to 7 days per week maximum	Dialyzing overnight can induce anxiety in caregivers and children from fear of disconnection or unattended machine alarms Virtually eliminates adverse intradialytic symptoms Greatest chance of achieving complete freedom from dietary and fluid restrictions possible Best for children with cardiac disease	Requires additional safety considerations Dialyze against 1.75 mmol/L dialysate calcium to protect against a negative calcium balance Higher frequency nocturnal HD may cause hypophosphatemia. Treat with oral supplements and/or add phosphate to the dialysate concentrate as a sodium phosphate enema Theoretical risk of “dialysis deficiency syndrome” (i.e., nonselective purification of essential plasma components). Consider surveillance and replacement of vitamins and minerals

These considerations are based on personal opinion
BP blood pressure, *HD* hemodialysis, *UF* ultrafiltration

Regardless, prior to going home, families should step down to an environment separate from the dialysis unit, in order to simulate the home environment as much as possible. Companies supplying the dialysis equipment will often provide considerable teaching materials and expertise, but invariably pediatric adaptation is necessary. Prior to discharge, an adherence contract signed by the child and their caregivers can be extremely helpful in formalizing the expectations and for reinforcing that any deviation will be taken very seriously.

Dialysis Equipment Most HD machines that are suitable for HHD require home water conversions to produce the large volumes of high-quality dialysate necessary for the dialysis treatment. Water conversion requires the installation of a cold-water outlet and a drain to allow the carbon filter, reverse osmosis unit, and dialysis machine to be fitted. A system for testing the water quality needs to be put in place. Typically, families test their water for chlorine and chloramine every session and then bring a sample for advanced testing to their monthly hospital clinic visits. The dialysis technician will test for chemicals, endotoxins, and microbiology.

The NxStage System One™ (NxStage Medical Inc., Lawrence, MA, USA) is a portable home dialysis machine that functions without home water modifications. Dialysis fluid is prepared in batches up to 60 l using the NxStage PureFlow™ SL integrated water purification and dialysis fluid production system, which uses ordinary tap water mixed with sterile-filtered concentrate to produce lactate buffered dialysis fluid. Premixed dialysis fluid is also available for home patients in sterile, 5L bags, with a variety of fluid compositions.

Potential Advantages of HHD over Conventional HD

HHD prescriptions have the potential to deliver a higher dialysis dose and allow for lower UF rates. The dialysis dose is important in lower body mass index (BMI) patients such as children. The HEMO study demonstrated a higher mortality risk in patients with the lowest BMI [81]. Increasing the dialysis dose as reflected by a higher urea reduction provided a greater survival advantage in the medium and small BMI groups [82]. The DOPPS review of 22,000 HD patients found that a higher dialysis dose, indicated by a higher Kt/V, was an independent predictor of lower mortality with a synergistic survival advantage with treatment time. Therefore, survival was most pronounced by combining a higher Kt/V with longer treatment time, such that for every 30 min longer on HD the relative risk of mortality was reduced by 7% [83]. An ANZDATA analysis found that the optimal dialysis dose for survival was a Kt/V greater or equal to 1.3 and a dialysis session greater or equal to 4.5 h. A single dialysis session prescribed for less than 3.5 h was associated with a higher mortality risk [84]; also see ▶ Chap. 78, “Adequacy of Dialysis.”

The UF rate during dialysis is also an important and significant factor in mortality. Movilli and colleagues demonstrated a critical safe point, with better survival with UF rates less than 12.37 mls/kg/h [85]. Patients who frequently exhibit intradialytic hypotension are at a higher risk of mortality compared to those who experience no hypotension [86]. Longer or more frequent dialysis sessions can prevent the deleterious consequences of excessive UFR or chronic hypervolemia.

Studies in Adults The majority of the literature on HHD is from observational or longitudinal studies, with only two randomized controlled studies to date [87, 88]. Reported improvements include reduced antihypertensive medication burden and lower incidence of left ventricular hypertrophy; improved anemia control and a lower average erythropoietin dose; a reduction in the use of phosphate binders and improved nutrition; and improved quality of life. During a matched cohort study comparing survival between nocturnal HD and deceased and living donor kidney transplantation, the proportion of deaths among the three was 14.7% for nocturnal HD, 14.3% for deceased donor transplantation, and 8.5% for living donor transplantation [89]. In a comparison with peritoneal dialysis, patients reported a similar perception of control over their kidney disease and did not consider HHD as a more intrusive treatment [90]. A meta-analysis of 681 pregnancies showed an inverse relationship between hours of dialysis and the risk of a preterm delivery or a baby born small for gestational age [91].

Studies in Children Pediatric data are scarce with mostly single-center reports; findings are largely consistent with the adult experiences. Short, 6 times per week HHD sessions resulted in reductions in BP and improved serum phosphate levels without changes to phosphate binder doses [2]. Dialyzing 5 h, 3 times per week, with a caloric intake of 150% of the recommended daily allowance for age led to improved growth [92]. Nocturnal HD, 6 nights per week, in four children age 10–19 years, achieved a weekly Kt/V of 7.2–13.6, fluid and dietary restrictions were completely liberalized, phosphate supplements were required to avoid hypophosphatemia, catch-up growth was achieved, and quality of life improved markedly [93]. Similar results were reported on six children age 11–17 years on nocturnal HD. BP control was variable, with two patients remaining on antihypertensives, and three patients requiring prophylactic midodrine to support their BP during UF [94]. All were dialyzed against 1.75 mmol/l calcium to prevent a net negative calcium balance [95]. Appetite, well-being, school attendance, physical and psychological health-related quality of life scores improved in all patients. However, caregivers' feedback highlighted the perceived burden and anxiety of dialyzing at home. The mother of one patient was psychologically and emotionally worn out after 1 year, necessitating respite arrangements of once weekly in-center treatments [94]. Finally a case of a 10 year old with presumed severe, irreversible cardiomyopathy treated with extended and then nocturnal HHD, reported completely normal cardiac function after 6 months of HHD [96]. It is postulated that the superior purification with minimal cardiovascular instability during UF was conducive to stopping and even reversing dialysis associated cardiac injury that we have come to accept from conventional HD prescriptions.

Risks and Complications Related to the Hemodialysis Procedure

While the approach to HD is well established and HD technology continues to advance, the HD procedure itself carries risk. Careful monitoring with safety devices and observation combine to assure a safe HD session. Despite safety as a top priority in all dialysis programs, patients may experience complications from the HD procedure.

Intradialytic Hypotension

Intradialytic hypotension is common, driven by complex pathophysiology including impaired hemodynamic compensatory responses with ineffective venoconstriction in the uremic milieu, reduced plasma refilling, a suboptimal metabolic stress response, inadequate ventricular refilling, lower myocardial contractile reserve, and impaired resting baroreflex sensitivity. In children the volume of blood within the extracorporeal circuit can be a significant proportion of the circulating volume. Tachycardia for any reason during the HD treatment will reduce diastolic ventricular filling and reduce myocardial perfusion. Blood and dialyzer membrane inflammatory reactions can result in early decompensation.

Noninvasive blood volume monitors provide a measure of the changes in relative blood volume (RBV), real-time during dialysis treatments. Several studies in adults have failed to demonstrate a critical threshold that can predict adverse events but found that irregularity of the RBV course, gradient of the RBV curve, and switching from an exponential to a linear RBV reduction were the most powerful predictors of intradialytic hypotension [97–99]. Likewise in children, the point of decompensation showed large intrapatient and interpatient variability; changes in heart rate and a steeper gradient of the RBV curve in the first hour were predictive of hemodynamic decompensation [50].

Consequences of Intradialytic Hypotension Intradialytic hypotension can cause symptoms that may become intolerable or severe such as cramps, headaches, and loss of consciousness. In adult dialysis patients, a "J" shaped curve exists between BP and mortality [100], with a fourfold increase in the relative risk of cardiac-related death in patients with predialysis systolic BP less than 110 mmHg compared with a systolic BP between 140 and 149 mmHg, and a 2.8-fold increase in relative risk for a cardiac-related death with post dialysis systolic BP less than 110 mmHg compared with systolic BP 140–149 mmHg [101]. Repeated intradialytic hypotension can result in recurring episodes of ischemia, accelerating the decline in residual renal function and multiorgan ischemic injury. In the heart, myocardial ischemia causes reversible, regional, left ventricular dysfunction, a phenomenon called myocardial stunning, with further intradialytic cardiovascular instability. Myocardial stunning has been demonstrated in children during conventional HD and the degree of myocardial dysfunction correlated with the UF rate and intradialytic blood pressure change [102].

Management of Intradialytic Hypotension Acutely, intradialytic hypotension requires immediate stepwise action dependent on the severity. This may include temporary suspension of the UF, providing a 5 ml/kg isotonic fluid bolus and early discontinuation of the dialysis treatment. Hemodynamic stability during dialysis can be improved by withholding antihypertensive medications on dialysis days, avoiding food during dialysis, and cooling the dialysate temperature to at least 0.5 °C below the patient's temperature prior to starting dialysis. UF profiles (decreasing step, decreasing linear, and alternating high/low UF rate) have been shown to be no better than a constant UF rate in preventing intradialytic symptoms or hypotensive episodes in children [103]. Manipulating the dialysis fluid composition can also improve hemodynamic stability:

- Switching to bicarbonate buffers compared with acetate buffers.
- Monitoring the plasma calcium levels and adjusting the dialysis fluid calcium concentration to avoid intradialytic hypocalcemia.
- Adjusting or profiling the dialysis fluid potassium concentration to avoid large potassium gradient changes during dialysis.
- Sodium profiling, utilizing a sodium concentration that falls in a step, linear, or exponential fashion. The higher dialysis fluid sodium counterbalances the rapid decline in plasma osmolarity due to clearance of urea and other small molecular weight solutes thus promoting plasma refilling. The low dialysis fluid sodium at the end minimizes the adverse effects of sodium loading.

Managing intradialytic hypotension will often require a combination of these interventions as opposed to trialing them in succession. In resistant cases, midodrine is a specific α-1 adrenergic agonist that mediates both arterial and venous constriction; it can prevent venous pooling while supporting central BP. Alternatively switching to HDF or augmented dialysis prescriptions may be required.

Dialysis Disequilibrium Syndrome

The disequilibrium syndrome is characterized by neurological changes, seizures, and possible risk for mortality in association with HD [104]. The reverse osmolar hypothesis suggests that disequilibrium occurs in the setting of rapid clearance of small molecules when the starting blood level of urea is very high. Rapid removal of urea from the blood causes a transient osmolar gradient for urea across the blood-brain barrier, drawing water into brain cells and leading to acute cerebral edema [105]. Since the disequilibrium syndrome appears associated with higher rates of dialytic clearance, the likelihood of this complication diminishes with lower rates of clearance, particularly for the first few HD sessions. Other maneuvers include giving infusions of mannitol during the HD session to compensate for the removal of other osmotically active particles (urea).

Fever and Infection

Fever in a HD patient raises concern for blood stream infection. This is more likely if the patient has an indwelling CVL. Not all patients with HD-associated infection will have fever and not all febrile HD patients will have a serious infection. The dialysis team should maintain a high index of suspicion and a low threshold to obtain cultures and provide antibiotics, at least until blood cultures results are obtained.

Vascular Access Related Infection

The presence of the foreign body that is the CVL, with passage through the skin, increases risk for infection. There are several potential infectious complications related to HD catheter use, of varying severity. Minor infections without systemic findings may be treated successfully with brief courses of antibiotics. More serious or recalcitrant infections will obligate the use of parenteral antibiotics for longer courses and, if the patient is at increased risk or the clinical status is not improving or is worsening, may necessitate removal of the HD catheter. Infection associated with AVF or AVG is much less common.

Catheter Exit Site Infection Despite appropriate local care at the exit site, the CVL predisposes to infection. Exit site infection commonly presents with pain, redness, or swelling at the exit site and drainage, possibly purulent. Exit site infection is less likely to present with concomitant fever; if the patient is febrile, one must have a higher index of suspicion for systemic rather than localized infection. The most common infectious agents causing exit site infection are skin flora, most often gram-positive bacteria such as *Staphylococcus* species. Swab sampling of any purulent drainage, sent for culture and gram stain, will help to clarify the specific bacterium and may guide therapy. Presumptive antibiotics would cover for the likely organisms, with choices adjusted depending on common local epidemiology and patient-specific history. In the absence of systemic findings and a judgment that the infection is superficial and localized to the exit site, oral antibiotics are a reasonable choice. Common options may include first-generation cephalosporin or clindamycin. Oral therapy can be adjusted based on culture results.

Catheter Tunnel Infection With a presentation similar to exit-site infection, HD catheter tunnel infection usually also demonstrates pain/tenderness along the track of the catheter itself, often with erythema and swelling. The patient may report warmth of the skin around the catheter and expanding area of redness. Fever is more common with tunnel infection than with infection localized to the exit site. Tunnel infection puts the patient at increased risk for bacteremia; parenteral antibiotics, providing coverage for gram-positive bacteria, should be employed and given the challenges of successfully clearing an infection around the foreign body, HD catheter removal may be required.

Catheter-Associated Blood Stream Infection CVLs are associated with the majority of bloodstream infections in HD patients [106]; bacteremia is roughly ten times more common in patients undergoing HD with a CVL compared to those with AVF or AVG. This is associated with greatly increased risk of mortality for those HD patients who develop sepsis, reported at 100 to 300-fold higher than for those in the general population [107]. Catheter-associated infection is more commonly seen with temporary HD catheters than with tunneled catheters; [108] the external cuff of the tunneled catheter serves as a barrier to penetrating infection and the length of the catheter tunnel also limits bacterial entry.

The majority of blood stream infections in HD patients, possibly up to 80%, result from gram-positive cocci such as coagulase-negative staphylococci or *S. aureus*, but gram-negative and polymicrobial infections are also seen [106]. Patients may present with fever, chills, general malaise or may have unexpected blood pressure instability during the HD session. There should be low threshold to obtain blood cultures and promptly begin parenteral antibiotic treatment. After obtaining blood cultures, most HD programs will empirically treat with broad-spectrum antibiotics to cover for both gram-positive and gram-negative bacteria; options include vancomycin and gentamicin or ceftazidime. Care is required when choosing antibiotics given the potentially negative impact of nephrotoxic medications on residual renal function, balanced with the necessity of treating a patient at high risk for complications. Once the infectious agent is identified and antimicrobial sensitivity pattern is available, one may narrow antibiotic therapy to a more specific option.

Many HD programs will add antibiotic locking solution to the regimen; antibiotic lock of the HD catheter will improve killing of bacteria inhabiting the biofilm within the HD catheter lumen. Antibiotic lock solutions blend heparin with an antibiotic such as vancomycin, ceftazidime, or cefazolin. The solution is instilled to the catheter lumen at the end of each HD session and can continue until the course of systemic antibiotic therapy ends or the HD catheter is removed.

Ideally, any infected venous catheter would be removed to permit clearance of the infection. In HD patients, removal and replacement of the vascular access is complicated by limited sites for replacement and the ongoing requirement for access to perform the HD sessions. Many infections can be cleared successfully with antibiotics, but in some cases the HD catheter must be removed. If the patient has evidence for sepsis, source control of infection by urgent catheter removal may be necessary. Patients with concomitant exit site and/or tunnel infection usually require catheter removal to fully clear the infection, even with less severe clinical signs and symptoms. Persistent fever/symptoms, or infection with agents that are known to be challenging to clear (e.g., *S. aureus*, *Candida* species, polymicrobial infections, resistant organisms), likely also will require catheter removal. After catheter removal, one must consider options for replacement to permit ongoing HD; this requires review of blood culture clearance, consideration of length of antibiotic treatment, clinical status of the patient, residual renal function, and alternative access sites for catheter re-insertion. For patients with persistently positive blood cultures, one may have to consider placement of a temporary catheter for HD; such a catheter could be removed more easily should it become re-infected prior to clearance of the bacteremia. Some patients may require catheter removal but are stable clinically and have evidence of having cleared their infection based on negative cultures. For such patients, one may consider catheter exchange over a guide wire. This approach preserves overall sites for vascular access by re-using the current access location and maintains continuity of access to avoid skipped HD session. Many adult HD programs have adopted catheter exchange over wire protocols for all stable patients with blood stream infection, noting increased rates of cure [109]. This approach may be more challenging in children for whom vascular access options are limited.

Infection Associated with AVF or AVG Compared to HD catheters, infections in patients who dialyze with AVF or AVG are infrequent [110]. While the rate is much lower, the infectious agents are similar. Risk increases in those patients with pseudoaneurysm, injury, or inappropriate puncture (e.g., injection of drugs of abuse). The button-hole technique for access puncture has also been associated with a higher rate of infection but not in all populations [40]. Given the lower likelihood of infection related to the access itself, as compared to those with HD catheter, a patient with evidence for bacteremia who dialyzes with AVF or AVG may be more likely to have endocarditis; consequently, extended course of antibiotics is recommended [111].

Blood Borne Virus Infections HD patients are at increased risk for infectious hepatitis. Of greatest concern is infection with hepatitis B or C; HD patients suffer increased morbidity and mortality with these infections related to the underlying immunosuppression of ESKD. Hepatitis is a significant infection control risk; HD units must engage in screening and appropriate isolation while also maintaining universal precautions to prevent transmission from undiagnosed patients.

Elevated Blood Pressure

High blood pressure is common in the HD unit [112]. Overwhelmingly, high blood pressure in a patient on maintenance HD stems from volume excess and improves with salt and fluid removal. Assessment of the volume status in a child on dialysis is described in detail in ▶ Chap. 74, "Assessment of Volume Status in Chronic Kidney Disease." Chronic hypertension requires a controlled and gradual lowering of the target weight and dietary sodium restriction. Persistent high blood pressure, after convincing efforts to reduce total body water and sodium excess, especially in those dialysis patients who retain their kidneys, may suggest renin-mediated hypertension. Such patients may benefit from renin-angiotensin-aldosterone system blockade, using angiotensin converting enzyme inhibitors, along with ongoing sodium/volume control.

Hemorrhage

Bleeding associated with HD relates to extracorporeal perfusion and the presence of a vascular access. Disconnection of the blood circuit tubing set from the vascular access puts the patient at risk for hemorrhage during the dialysis procedure. Monitors on the dialysis machine note the sudden change in pressure within the blood circuit at the time of disconnection and stop the blood pump while sounding an alarm; this greatly reduces the chances of rapid exsanguination which could occur with a venous limb disconnection and continued blood pump rotation. A more common scenario for blood loss in the dialysis unit occurs with clotting of the blood circuit during the session or mechanical failure of the hemodialysis device, after which bedside staff cannot return the volume of blood in the extracorporeal circuit to the patient. Careful assessment of the patient may show symptoms related to volume loss requiring volume expansion with crystalloid or, in severe cases, blood transfusion; if the patient is asymptomatic, treatment is expectant.

Air Embolism

Air embolism is a potentially serious complication in which a breach of the blood circuit, most commonly at a connection site, entrains air into the blood flow system that then enters the patient [113]. This can lead to acute respiratory compromise similar to a thrombotic embolism. Acute management includes immediate cessation of the dialysis procedure, 100% oxygen to the patient, and critical care support if indicated. The air detection system on modern dialysis equipment makes air embolism very rare, but its seriousness requires all dialysis providers to have a high index of suspicion.

Water-Related Complications

Contamination of a dialysis unit water system, with either microbes or biochemical contaminants, can have devastating effects on multiple patients simultaneously. For example, chloramine, a by-product of chlorine, when not appropriately removed from dialysis water, can cause severe hemolytic reactions and death [114]. Given this risk, dialysis staff must check for the presence of chloramine, which the water treatment system normally removes quite effectively, multiple times a day. The entire dialysis water system must undergo frequent monitoring and ongoing preventive maintenance to assure its integrity and the safety of the patients.

Intradialytic Cramping

Cramping during the HD session is a common patient complaint. It appears to be associated with higher rates of UF and may therefore be related to reduced muscle perfusion. In addition, intradialytic electrolyte imbalances and changes may also be a cause. Some report that abdominal cramping is more common when patients eat or drink during dialysis sessions. Preventive measures, such as working with patients to limit interdialytic weight gain leading to the need for high rates of UF, may be the best approach. Medications such as quinine, used more commonly for adults, have fallen out of favor due to side effects. Sodium modeling may limit muscle cramping on dialysis [115] but may also limit negative sodium balance during the session, putting the patient at risk for volume overload and high blood pressure [116, 117].

Long-Term Outcomes of Chronic Hemodialysis in Children

While advances in dialysis technology have improved outcomes even for the youngest children, mortality remains high and the morbidity and burden of care cannot be underestimated. Optimal management of children on dialysis requires a multidisciplinary team and consideration of the child and family's expectations. Most importantly, minimizing the time on dialysis by early or even preemptive renal transplantation is currently the best option for ESKD patients.

With few high-quality randomized trials, clinicians are reliant on prospective cohort studies and international registries to inform and improve management strategies.

Cardiovascular Disease and Survival

Children on HD have a mortality rate that is 30-fold higher than their age-related healthy peers [118], and cardiovascular disease accounts for over 20% of deaths. Cardiovascular events occur in approximately 25–35% of children on chronic HD and include arrhythmias, valvular heart disease, cardiomyopathy, and sudden death [119]. Left ventricular hypertrophy (LVH) has been reported in 40–75% of children on maintenance dialysis [120]. Risk factors include chronic hypervolemia, a hyperdynamic circulation secondary to AVFs or anemia, and vascular calcification leading to increased arterial stiffness [121]. Cardiac hypertrophy and continued mechanical stress can trigger myocardial remodeling and reduce coronary flow reserve predisposing the heart and other organs to ischemic injury.

Vascular and valvular calcification can begin in CKD but is more prevalent in dialysis patients, with an accelerated progression of calcification that increases with time on dialysis [119]. Coronary calcification has been reported in 20–30% of children on dialysis. While traditional cardiovascular risk factors such as dyslipidemia and inflammation are associated with intimal disease or atherosclerosis [122], the uremia-related risks, in particular dysregulated mineral homeostasis including high calcium, phosphate, PTH, and vitamin D as well medications used to treat MBD including calcium-based phosphate binders and vitamin D, are associated with medial calcification or atherosclerosis [123–125]. The etiology and consequences of vascular calcification are discussed in detail in ▶ Chap. 72, "Chronic Kidney Disease – Mineral and Bone Disorder (CKD-MBD)." Atherosclerosis can lead to increased vessel stiffness, high systolic blood pressure, left ventricular hypertrophy, and reduced coronary blood flow. Improving phosphate clearance by using intensified dialysis regimens is shown to reduce the prevalence of calcification and LVH [73, 126].

Nutrition, Growth, and Development

Malnutrition and poor growth are seen in children on HD, particularly if they have been underdialyzed, and have been associated with mortality. There is a 30–50% risk of short stature in children on chronic dialysis. [127, 128] Mechanisms of poor growth include reduced appetite due to dysregulation of the hormones regulating appetite and satiety and resistance to growth hormone. Nutrition in CKD and dialysis is discussed in detail in ▶ Chap. 71, "Nutrition, Growth, and Development." The normalized protein catabolic rate (nPCR), an indirect measure of daily protein intake in stable dialysis patients, and derived from formal urea kinetic modeling or calculated from blood urea nitrogen (BUN) measurements [127], can be used to guide protein intake; details discussed in ▶ Chap. 71, "Nutrition, Growth, and Development." However, it may be influenced by factors other than nutrient intake [129] and should be interpreted in combination with a review of weight gain and the dietary history [130].

Children with CKD may have low-average neurocognitive and academic outcomes, and cognition appears to worsen with advancing CKD, with children on dialysis having the poorest performance [131]. Neurocognitive disorders in CKD are discussed in detail in ▶ Chap. 71, "Nutrition, Growth, and Development."

Impaired Health-Related Quality of Life (QoL)

Children on dialysis are exposed to treatment regimens that are long-term, complex, and highly intrusive. They may suffer from fatigue, sleep disturbances and pruritus, may require multiple hospital admissions, and have long-term dietary and fluid restrictions, all of which can disrupt home and school life, reduce the child's social contact with their peers and families, and contribute to a poor QoL [132–134]. Children with CKD are at risk of cognitive impairment and poorer educational, vocational, and psychosocial outcomes compared with their well peers, which have consequences through to adulthood [135]. In the longer term, young adults who had received dialysis during their childhood were more likely to be unemployed, and less likely to be in a long-term relationship [136]. The Standardized Outcomes in Nephrology (SONG) initiative recognized that survival and "life participation" were important treatment goals for children [137], stressing the importance of working in partnership with the child and family to help them achieve an optimal QoL.

Other Long-Term Complications

Dialysis Related Amyloidosis Amyloid accumulation is a disabling, progressive condition caused by amyloid accumulation predominantly in the osteoarticular systems that can lead to carpal tunnel syndrome and spondyloarthropathy and accumulation in the vessel walls and heart contributing to uremic cardiovascular disease. It is primarily related to the accumulation of β2-microgolbulin, a middle molecular weight (11.6 kDa) protein that is primarily cleared by convection. Hence, it tends to accumulate in patients on conventional HD but is effectively removed by HDF, providing around 70% better removal than conventional HD [70].

Dialysis-Related Carnitine Disorder Levocarnitine (L-carnitine), a critical co-factor for normal energy production in cardiac and skeletal muscle, is rapidly removed by HD [138] resulting in an abnormal acylcarnitine: free carnitine ratio. Low carnitine levels may be associated with intradialytic hypotension, cardiac dysfunction, fatigue, muscle cramping, reduced exercise tolerance, and anemia [139]. L-carnitine supplementation is recommended for patients with clinical symptoms even in the absence of low plasma carnitine levels [140].

Hyperhomocysteinemia Homocysteine, a non-protein forming amino acid that results from methionine metabolism, accumulates from early stages of CKD. A meta-analysis reported a positive association between hyperhomocysteinemia and atherosclerosis, ischemic heart disease, stroke, and thrombosis [141], but others have found no significant or even an inverse association between plasma homocysteine levels, cardiovascular events, and mortality in ESKD patients [142]. Treatment options include folate and vitamin B12 supplementation to achieve supranormal plasma levels, or intravenous N-acetylcysteine, [143] or improved clearance with high-flux dialyzers [144].

Conclusion

Technical advances have facilitated chronic HD treatment in even the youngest children, and improvements in medical and nursing skills have made HD safer and more effective than ever before. Intensified HD with extended hours, home HD as well as in-center HDF have improved outcomes compared to conventional HD regimens. Nevertheless, children on HD have a high morbidity and mortality, accruing a significant burden of cardiovascular risk factors. Thus, even as efforts continue to improve HD technology, nephrologists must aim for preemptive kidney transplants where possible, using dialysis only as a bridge to transplantation.

Abstract

Infant dialysis remains one of the greatest challenges in pediatric nephrology due to the difficulties encountered during the management of patients of small size, and the need for complex and costly resources in order to provide good medical care. There are number of factors which make infant dialysis special. Of importance is that kidney failure in the first months of life is in most cases associated with a variety of other anomalies or comorbid conditions. The severity of the accompanying conditions impacts the likelihood of survival and influences the decision whether to initiate dialysis. Once the decision has been made to start dialysis, issues of growth and development, infectious and noninfectious dialysis complications, quality of life, and preparation for transplantation need to be addressed. One of the key treatment challenges is providing optimal nutrition as it is the predominant factor affecting growth, psychomotor, and cognitive development in infancy. Peritoneal dialysis (PD) remains the modality of choice prescribed to infants worldwide, due to its simplicity, avoidance of vascular access, partial independency of hospital setting, better preservation of residual kidney function, and fewer dietary and fluid restrictions. If PD is contraindicated or not feasible, hemodialysis is also a successful option.

Infant dialysis · Epidemiology · Ethics · Nutrition · Growth · CKD-MBD · Long-term outcome

Introduction

Advances in peritoneal dialysis (PD), hemodialysis (HD), and kidney transplantation over the decades mean that it is possible to treat even infants with end-stage kidney disease (ESKD) [1]. However, this comes at a cost because infants demonstrate higher rates of hospitalization, morbidity, and mortality when compared to older children on dialysis [2]. Kidney transplantation is the preferred kidney replacement therapy (KRT) for all children with ESKD; however, since kidney transplantation in infants is technically limited by patient and vascular size, all infants with ESKD need chronic dialysis until they reach approximately 10 kg in body weight [3]. Impaired growth due to inadequate nutrition, poorly controlled CKD-mineral bone disorder (CKD-MBD), and other ESKD-associated conditions remain major clinical issues in infants on dialysis [4, 5, 6]. Furthermore, there are ethical debates regarding the initiation and maintenance of chronic dialysis in ESKD infants with complex comorbidities [7]. Thus, infant dialysis presents one of the greatest challenges in the field of pediatric nephrology (Table 1).

This chapter will address the current knowledge on the epidemiology, ethics, when to start and stop dialysis, approaches to PD and HD, growth and nutrition, management of CKD-MBD, and long-term outcomes of infants requiring chronic dialysis therapy.

Table 1 Challenges in infant dialysis

More than 50% are diagnosed antenatally
Prematurity or low birth weight common
Decisions may be needed regarding commencement or withholding of dialysis
Pre-emptive transplantation is not possible
Preservation of access sites is a particular problem
Feeding and growth:
Need to support a high nutritional requirements and growth rate
Liquid diet affects dialysis program
Vomiting common
Enteral feeding frequently required
Calcium requirements high
Salt depletion may be an issue
Burden of care
Limited clinical experience in most centers
No evidence-based studies

Epidemiology

Number of Infants Initiating Chronic Dialysis

Before the early-1980s long-term outpatient dialysis could not be undertaken in infants with ESKD [8]. However, improvements in dialysis technology and clinical expertise mean that this is now a practical option for most infants. Based on registry reports from the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) and the European Society of Pediatric Nephrology and European Renal Association-European Dialysis and Transplant Association (ESPN/ERA-EDTA), the numbers of infants initiating chronic dialysis were 901 from 1992 to 2012 and 1063 from 1991 to 2013, respectively [9, 10]. Furthermore, a report from the NAPRTCS registry indicated that the proportion of infants initiating chronic dialysis increased from 13.4% in the period of 1992–2001 to 14.9% in the period of 2002–2011 [9]. A similar trend was also observed in data from the United States Renal Data System (USRDS) registry. The numbers of infants initiating chronic PD were 543 from 1990 to 1999 and 1180 from 2000 to 2014, respectively [11]. Thus, the number of infants initiating chronic dialysis has recently increased in high-income countries.

However, health disparities in access to KRT among children with ESKD still exist between children of low- and lower-middle-income countries as compared to higher-income ones [12]. Since infants with ESKD are more medically complex and need more resources, the number of infants initiating chronic dialysis is largely influenced by economics: the International Pediatric Peritoneal Dialysis Network (IPPN) reported that the age distribution of the children undergoing chronic dialysis markedly varied with economic wealth (expressed as per-capita gross national income), with almost 1 of 5 patients in the high-income countries, but only 1 in 50 in the low-income counties, being younger than 12 months of age (Table 2) [13]. Analyses of European middle-income and high-income countries showed that there were differences between countries in their ability to accept and treat infant ESKD patients, which were largely explained by differences in public health expenditure [14]. Thus, the number of infant initiating chronic dialysis is strongly affected by a country's gross national income and public health expenditure.

Primary Diagnoses and Comorbidities

Based on registry data from NAPRTCS, ESPN/ERA-EDTA, and USRDS, the most common primary diagnosis in infants requiring chronic dialysis therapy is CAKUT (including kidney hypoplasia/dysplasia and obstructive uropathy), comprising around half the cohort [9, 10, 11]. Other causes are cystic kidney disease (mainly, autosomal recessive polycystic kidney disease), neonatal cortical necrosis, congenital nephrotic syndrome, kidney venous thrombosis, hemolytic uremic syndrome, primary hyperoxaluria type 1, and angiotensin-receptor blockade fetopathy [11, 15]. Thus, causes of ESKD in infants differ in comparison to older children with ESKD [16].

Comorbidity is particularly common in this age group, with a reported incidence of up to 75%

Table 2 Gross national income and age at start of dialysis in chronic peritoneal dialysis patients who were enrolled in the IPPN registry between April 2007 and March 2012

Age at start of dialysis (%)	Gross national income in $000s per capita			
	>28	18-28	12-18	<12
<1 years	19	18	16	2
1-3 years	11	15	11	6
3-6 years	8	14	10	16
6-12 years	21	28	35	38
12-18 years	37	23	28	37

Adapted from Ref. [13] with modifications

depending on the population studied and how comorbidity is defined. Syndromes, chromosomal abnormalities, developmental delay, cardiovascular disorders, lung abnormalities including pulmonary hypoplasia, neurological disorders, and liver disease are the commonest [14, 15, 17]. Thus, many infants requiring chronic dialysis therapy also require care from many medical teams because of their complex conditions.

The Ethics of Infant Dialysis

Advances in resources to diagnose abnormalities in utero have outstripped our ability to use the information to predict fetal and neonatal outcomes. Ultrasound (US) can detect the majority of cases of congenital abnormalities of the kidneys and urinary tract (CAKUT), which occur in 1–4 per 1000 pregnancies. Most of these are benign. US can also detect cystic kidney diseases. Genetic studies may be helpful for diagnosis, although rarely so for CAKUT unless there are associated comorbidities. Although kidney sizes and appearances, bladder pathology and amniotic fluid volume may be used to counsel families as to the potential that their child will need KRT in the future, there is no infallible method that enables clinicians to be certain whether this is likely to be an immediate requirement or one that is many years away [18].

For these reasons, the perinatal period is a time that is fraught with anxieties and difficult decisions for the family. Miscarriage may occur with severe kidney abnormalities but the incidence of this is unknown. Antenatal surgery has been proposed but its success is variable and unproven [19] Termination may be discussed in those pregnancies that are thought by the managing team to be at very high risk. The family, in these circumstances, will have to live through months of uncertainties, and will have expectations for their infant that may or may not be realistic [20].

As well as parental preconceptions (which may be correct or incorrect) about the future for their infant and management after birth, there are factors that may bias the attitudes of the medical team as well, and lead to ethical issues. For the infant needing KRT, a decision may need to be made about its appropriateness. Many infants have associated comorbidities, and these, together with uncertainty for individual outcome, carer burden and resources, can contribute to difficult decision making.

The European Paediatric Dialysis Working Group (EPDWG) addressed these issues and suggest in their guidelines that comorbidities and predicted future quality of life for the infant and their family; availability of resources, both medical and those of the family support structure; and prognosis and possibility for future transplantation should be taken into consideration when deciding whether to go forward with dialysis. The parents should be actively involved in the decision-making process [21].

Countries have produced guidelines to help the multidisciplinary team in determining the management of severely ill children, and these apply equally to all causes of illness. The overriding principle is that the current and future treatments must be “in the child’s best interests,” i.e., that benefits outweigh burdens; any potential harm is minimized; and the child is treated fairly and justly. Future quality of life, which has been defined as survival without life support, life outside of hospital, ability to develop relationships, and ability to gain pleasure from life is deemed more important than chances of survival. There is no right or wrong answer to these dilemmas, and the multidisciplinary team must work with the family to obtain a satisfactory outcome [7].

When to Start Dialysis

The majority of infants with CKD are affected by CAKUT. As abnormal tubular function predominates over glomerular dysfunction, most infants are salt and water losers and continue to pass urine, even in large quantities, in the face of very low Glomerular Filtration Rates (GFRs). There are some infants who do not pass urine, such as those with renal agenesis or renal tubular dysgenesis, when dialysis is clearly needed to prolong life. However, where there is adequate urine, good dietary input and medical therapy can enable the infant to thrive, with good metabolic control for extended periods [22]. However, given the rarity of such severely affected infants, many teams will not have the experience or resources, particularly pediatric kidney dieticians, to manage these infants conservatively.

There are factors that help in prediction of the potential for kidney recovery. Many infants with CAKUT are premature or of low birth weight, with the potential for damage to the ongoing development of the glomeruli as a result [23]. There may be further insult to the kidney from obstruction or UTI; or from respiratory compromise due to lung hypoplasia. On the other hand, as blood flow to the kidney improves and kidney maturation continues, this may be overridden by a steady improvement in kidney function.

The improvement in GFR that is seen in the first few weeks of life may be enough to keep the infant from dialysis until they have grown sufficiently to postpone the technical difficulties associated with small size. This is substantiated by European data that shows that of 238 neonates commencing dialysis in the first month of life, 19 (8% of all neonates) were able to stop it. When a nadir in creatinine is reached, a decision can be made about the need for dialysis to preserve metabolic control, fluid balance, and growth [24].

A key management point is to ensure adequate salt and water administration. Dehydration and poor kidney perfusion is a frequent accompaniment of CAKUT, and the temptation to restrict both salt and water must be avoided, even with very low GFRs in these infants [25].

Choice of PD/HD

Although kidney transplantation (KTx) is the modality of choice for both children and infants, in the latter group it is technically limited due to patient and vascular size, and as a consequence the majority of infants have to initiate either PD or HD. Both methods are feasible in infants, but PD is usually preferred. According to registry data PD served as the initial KRT therapy in 85–92% of infants in the USA and Europe [26, 15]. Advantages of PD include partial independence from the hospital setting, no need for vascular access, greater hemodynamic stability, better preservation of RKF, and fewer dietary and fluid restrictions. Drawbacks of PD are associated with burden of caregiver responsibility for conducting the treatment and requirement of a clean home with adequate storage space [27]. Contraindications for PD include conditions which compromise the abdominal cavity and peritoneum such as an obliterated peritoneal cavity, omphalocele or bladder extrophy. Hemodialysis is much less common in infants, although the use of chronic HD has been reported in children less than 10 kg [28]. Based on registry data, HD was the first dialysis modality in almost 14% of infants dialyzed in Europe and less than 3% in those from the USA [9, 10, 26]. Reluctance to utilize HD in small children is mainly due the need for long-term central venous catheters, which increases the risk of infectious and thrombotic complications. The latter may lead to damage to the central veins in patients who are potentially facing decades of KRT. An Italian study of infants receiving HD via CVCs

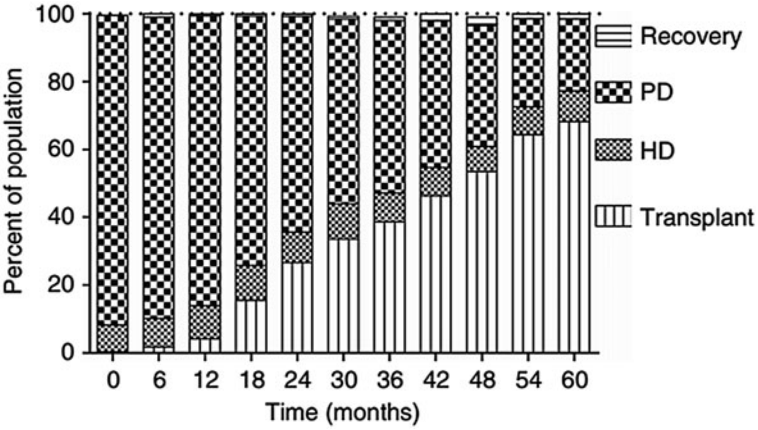

Fig. 1 Changes in treatment modality over time in infants who initiated dialysis in the neonatal period (adapted from Ref. [15] with modification)

confirmed CV thrombosis in 38% of patients [29]. Other important drawbacks include hemodynamic instability during hemodialysis sessions, blood loss, and exposure to blood products. The need for providing sufficient nutrition with fluid-based formulas in non-polyuric infants creates a problem of adequate ultrafiltration, which often necessities prolonged or frequent dialysis sessions. As a result of these disadvantages, it is usually only the infants with absolute contraindications for PD or patients with metabolic conditions in which HD gives better clearance, who initiate KRT with HD. The transition from one dialysis modality to the other is more frequent in infants compared to older children due to this high complication rate. In the ERA-EDTA report, one quarter of children between 0 and 4 years changed from PD to HD [30]. According the report of ESPN/ERA-EDTA, IPPN, Australian and New Zealand Dialysis and Transplant (ANZDATA), and Japanese RRT registries, 39.4% of the patients, who initiated KRT in the neonatal period, switched treatment modality during the first 2 years of life, most commonly due to KTx (Fig. 1) [15].

Peritoneal Dialysis

PD Catheters: Choice and Placement

Successful PD requires reliable access to the peritoneal cavity with a well-functioning dialysis catheter. Among the features potentially influencing catheter performance are catheter type, exit site orientation, placement technique, timing of first catheter use, and exit site care. Ideally, the placement technique, the characteristics of the PD catheter, and the care of the catheter should result in few mechanical and infectious complications. Generally infants are at increased risk of catheter related infectious and noninfectious complications. In a worldwide PD catheter outcome study, nearly 40% of infants required catheter revision, most commonly within 60 days of catheter placement [31]. The predisposition for young patients to experience access complications or failure may be related to a number of factors, including a lack of substantial abdominal musculature resulting in hernia formation, the use of diapers, and possibly the presence of immunodeficiency (such as low IgG levels), which may increase the likelihood of infection [31]. In order to decrease the rate of potential complications, a PD catheter should be placed by an experienced surgeon with expertise in infant catheter placement [32].

The first step in PD planning is catheter choice. There are various types of PD catheters available. The most widely used include single or double cuffed Tenckhoff catheters with either a straight or swan-neck subcutaneous portion and curled or straight intraperitoneal part. Whereas a double cuff catheter is usually preferred due to the ability to fix the external cuff in the subcutaneous tissue, in infants weighing less than 2–3 kg single cuff catheters can be used. It is also acceptable to place a single cuff vascular catheter in the peritoneal cavity if a Tenckhoff catheter is not available

[33, 34]. The length of the catheter has to be adjusted to patient size. The ideal length is measured by placing the internal cuff lateral and 1 cm above the umbilicus and then down to the symphysis pubis. In order to prevent contamination the exit site has to be positioned lateral or downward pointing and at a distance from any abdominal wall stoma or the diaper area [32].

When a PD catheter is inserted, a perioperative first-generation cephalosporin or gentamicin (refer to ISPD guidelines [32]) should be administered. The catheter can be placed either by open or laparoscopic procedure, with the former option being preferred in infants. A para-median or lateral entry into the peritoneum is performed with fixation of the internal cuff in the rectus muscle. If possible an omentectomy should be performed to prevent the omentum from clogging the side holes of the catheter. Closure of a patent processus vaginalis may be performed prior or at the time of PD catheter placement in order to prevent hernia formation. Immobilization of the catheter by dressing allows healing and prevents pulling and tearing. A delay of 2–3 weeks in dialysis following catheter implantation is beneficial, in order to prevent leaks and hernias. Fibrin glue at the internal cuff has been shown to decrease leaking complications [35]. As a gastrostomy button/tube is frequently needed to support nutrition, advanced surgical planning for PD catheter and gastrostomy placement is extremely important, and discussions between surgery and nephrology team members should address the optimal timing of both procedures. If possible, gastrostomy placement should either precede or be performed at the same time as the PD catheter insertion in order to reduce peritonitis risk [36–38]. If a gastrostomy has to be placed in a patient already on PD, an open procedure is necessary, and prophylaxis with antibiotic and antifungal therapy should be initiated. In such a case, it is advisable to hold dialysis for 2–3 days post-gastrostomy placement [32].

PD Prescription

There is no single optimal PD prescription, but the goals are to meet patient's ultrafiltration and solute clearance needs in order to optimize growth and development. Both continuous ambulatory peritoneal dialysis (CAPD) and automated peritoneal dialysis (APD) are feasible in infants. When first initiating, PD manual exchanges may be needed as fill volumes are likely to be very small; the initial fill volume of 10 ml/kg (absolute amount 20–30 ml per exchange in 2–3 kg infants), is lower than the minimum fill volume of 60 ml that makes up the “dead-space” of the tubing of cyclers. Fill volumes are increased gradually over days or weeks depending on the patient's tolerance. Once a fill volume of 80–100 ml is achieved, APD can be introduced. The target fill volumes in infants should not excide 600–800 ml/m^2, as higher values are associated with increased risk of hernia, leakage, and gastroesophageal reflux (GER) [21, 32, 36]. For these reasons the intraperitoneal pressure should not exceed 10 cm H_20 in this age-group. Low fill volumes result in a rapidly diminishing osmotic gradient and thus limited ultrafiltration; hence dwell times of 1 h or less are frequently utilized. Dwell times as short as 20 min may be used in neonates when rapid removal of small solutes is desired. In the setting of chronic PD, an initial empiric dwell time of 1 h is often used in infants, although consideration has to be made for clearance of molecules such as phosphorus which require longer dwell times. APD is the preferred modality in infants due to its flexibility and ease of making frequent adjustments in the rapidly growing patient. In order to preserve peritoneal membrane function it is advisable to use either fluids with the lowest possible glucose concentration that are “biocompatible,” with low glucose degradation products [39, 40, 5]. Calcium concentration (available as 1.25 or 1.75 mEq/l) may need to be individualized to provide sufficient calcium for growth and prevention of secondary hyperparathyroidism. Polyuric infants will usually require long dwell times to optimize solute clearances, while anuric patients need frequent exchanges and short dwell times to increase ultrafiltration.

Neonates and infants can experience excessive losses of protein via PD with studies demonstrating average daily losses of 250 mg of protein per kg of body weight or almost twice the peritoneal protein losses seen in older children. A dietary protein of at least 1.8 g/kg/day for the first 6 months of life is recommended, taking into account the dietary reference intakes (DRI) and peritoneal losses.

PD-Related Complications

Infant dialysis is associated with a high mortality and morbidity. This is influenced by a high incidence of multiple comorbid conditions, technical difficulties of infant dialysis, and high rates of both infectious and noninfectious complications [9, 15, 31]. The most common complication of PD continues to be peritonitis, with its incidence being much higher in infancy as compared older age groups [9, 11]. Catheter-related complications include mechanical problems such as catheter blockage or migration or PD fluid leakage such as with pleuroperitoneal or pleuropericardial fistulae, and exit site or tunnel infections. In the recent IPPN analysis, the overall catheter survival rate was significantly lower in infants compared with children in the older age groups [31]. In addition, the presence of any ostomy (including gastrostomy) is associated with a 55% higher risk for catheter failure [31]. As the underlying disease in most infants on dialysis is associated with tubular dysfunction causing polyuria and salt depletion (also aggravated by the loss of sodium in dialysate), hypotension, with its significant risks of cerebral or optic ischemia, is common in infants on PD [41]. For this reason many infants will require additional sodium supplementation. In contrast, chronic hypervolemia is common in anuric infants and may lead to hypertension and cardiac impairment [21].

Hemodialysis

Optimal hemodialysis (HD) in small babies is challenging and requires a thorough understanding of their unique age-related physiology. Many HD machines require double-lumen access with disproportionally large lines with a relatively large extracorporeal circuit, which necessitates blood or saline priming, thereby promoting HLA sensitization. The new machines designed for small babies (CARPEDIEM, NIDUS), which are currently being used in PICU for acute dialysis, allow successful delivery of continuous and intermittent diffusive blood purification modality to very small, using small CVLs, no blood primes, and excellent concordance between delivered and prescribed ultrafiltration. In future, these machines may be modified for maintenance dialysis in infants [42, 43].

HD Catheters

For chronic dialysis in infants soft blunt-tipped dual-lumen catheters are placed into the central veins. The preferred site is the right internal jugular vein, with the tip in the right atrium. Alternative sites are left internal jugular vein, subclavian, and femoral veins. Subclavian vein catheterization has been associated with a high risk of thrombosis, stenosis, and a shorter catheter survival, while femoral sites have a higher risk of exit site infections and bacteremia. The commercially available CVCs for neonates and infants include dual lumen 6 Fr catheters for neonates, 7 Fr for those weighting 3–6 kg and 8 Fr for infants >6 kg. If the body weight is <5 kg, single-lumen access may be more appropriate keeping in mind that the resistance of a tube, and therefore the blood flow, is inversely proportional to the fourth power of the radius (Poiseuille's law). Neonates can be dialyzed via the umbilical vein using a 5.0–8.5-Fr umbilical venous catheter. Two single lumen catheters placed into two veins (i.e., femoral veins) is possible. One catheter is advanced into the inferior vena cava ("venous" infusion), while the other is positioned in the internal iliac vein ("arterial" draw) [44].

HD Prescription

The HD prescription must be calculated and individualized for each patient to provide adequate solute clearance and fluid removal. Components of the HD prescription include the dialyzer, tubing (i.e., the HD circuit), blood flow rate, dialysate composition and flow rate, treatment duration and frequency, fluid removal goal, and anticoagulation. The dialyzer surface area should be equal to 75–100% of patient's body surface area in order to provide adequate fluid and solute removal and to minimize extracorporeal blood volume, which cannot exceed 10% of the patient's total blood volume (together dialyzer and tubing). As total blood volume is equal to 100 ml per kg in neonates and 80 ml/kg in infants, line priming with saline, albumin, or blood is usually needed. Effective membrane areas in dialyzers for infants range from 0.2 m^2, while neonatal lines allow priming volumes as low as 30 ml [45, 46]. The initial blood flow rate should not exceed 2–3 ml/kg/min, with a gradual increase to 5–8 ml/kg/min, depending on the patient's tolerance. The maximal ultrafiltration should not go beyond 5% of body weight per session or 1–2% of body weight per hour. In order to maintain good hemodynamic and nutritional status often long or frequent sessions are required [29]. The choice of dialysate should be individualized; in most centers bicarbonate is the standard buffer with its concentration varying between 32 and 40 mmol/L. Anticoagulation includes heparin, Low Molecular Weight Heparin (LMWH), or citrate depending on availability and center experience.

HD-Related Complications

The most common HD-related complications are associated with catheter performance, including poor blood flow due to malposition or thrombosis, and catheter infections. Six single center studies based on data of 9–11 infants report diverse catheter outcomes with median catheter survival ranging from 21 to 390 days and infection rate from 10 to 0.3 per 1000 CVC days [28, 47–50]. Central venous stenosis is a potentially life-limiting complication of chronic dialysis in children because it limits the efficiency and duration of peripheral access routes and reduces the number of vessels suitable for future catheterization and fistula placement. The risk of acute HD complications including intradialytic hypotension, air embolism, hemolysis, and acute anaphylactic reaction is similar to that in older age groups.

Growth and Nutrition

It is universally recognized that maintaining normal growth in infants on dialysis is a challenge for the multidisciplinary team. Some factors, such as the influences of comorbidities, prematurity, and low birth weight cannot be easily overcome. Other factors such as oligo-anuria, lung hypoplasia, episodes of sepsis and operative interventions aggravate feeding difficulties. However, the most important aspect to address in all infants on dialysis is nutritional intake. Nutrition is the predominant factor affecting growth in infancy, exceeding the influence from growth hormone during the first 2 years of life.

Anorexia and GER accompanied by recurrent vomiting are common. The rate of growth is greater than at any other time of life, being as high as 25 cm per year at birth, 18 cm per year at 6 months of age, and 12 cm per year at 12 months of age. It is not surprising therefore that without intensive nutritional management, loss of height standard deviation score (SDS) of as much as 0.6 SD per month can occur. This period without linear growth is very difficult to compensate [51].

]Many infants are unable to achieve adequate nutritional intake without resource to enteral feeding, although vomiting may mean that target formula volumes may not be achieved despite the use of a nasogastric (NG) tube. Vomiting may be due to a "full abdomen" from the peritoneal dialysate, constipation, and abnormal clearance of gastrointestinal hormones that control stomach emptying and GER. Medications such as prokinetic agents, proton pump inhibitors, and 5HT3 receptor antagonists may help with symptom reduction.

Concentrating infant formulas may reduce vomiting and provide the nutritional prescription in a smaller volume, e.g., increasing the formula concentration from 13% to 15% means that the volume can be reduced by 20 ml/kg/day. This is also important in the oliguric infant. Vomiting may also be reduced if feeds are given by slow continuous drip overnight with oral or bolus tube feedings offered during the day [52].

There are recent guidelines on the use of a gastrostomy tube in preference to an NG tube. In summary, a gastrostomy is less easily displaced; is hidden under clothing thereby removing the stigma of a chronically ill child; it is not associated with abnormal development of oromotor skills; can be safely used to feed overnight; and is associated with better growth, perhaps as a result of a decreased frequency of vomiting [5, 38].

Protein and Energy and Requirements

During PD, transperitoneal protein losses mean that the feed content of protein should be increased above the requirements for the normal population of the same age. These losses are increased further during peritonitis. Protein requirements for HD are lower than for PD patients, although there is amino acid loss in dialysate. The dietary aim is to enable normal growth and serum albumin, to maintain a urea level below 20 mmol/l and to control serum phosphate levels. Energy requirements do not differ from those for children with normal kidney function [53]. Further details on nutritional management are provided in ▶ Chap. 71, "Nutrition, Growth, and Development."

Salt and Water

Many infants on dialysis have CAKUT, and can continue with urinary salt and water losses for some time. In addition, losses into PD fluid are also important. Hypotension is common. Sodium supplementation and provision of adequate fluid intake in such infants seems counterintuitive, but chronic salt depletion is a well-known influence on growth [51].

CKD-MBD

Control of CKD-MBD is another challenge. The recommended daily calcium balance in the first year of life is 500–600 g, which is higher than at any other age, so that a baby on PD on a standard whey-based infant formula may be barely receiving adequate calcium, and rickets is common. Also what is frequently overlooked is that the normal range for plasma calcium is higher in the first year of life than at any other age [54].

Plasma calcium and phosphate can be manipulated by modifying dietary and dialysate intake, in addition to the use of phosphate binders and vitamin D [55]. The dialysate calcium can be increased from neutral (1.25 mmol/l) to higher levels of 1.75 mmol/L to allow diffusion of dialysate calcium into the blood. Like calcium, normal values of serum phosphate are also higher in infancy, but calcium containing phosphate binders are still often needed.

The normal population Reference Nutrient Intake (RNI) for vitamin D in the first year is 8.5 μg/day reducing to 7 μg/day at 7 months (340–280 IU). Standard whey-based infant formulas contain 1.2 μg (48 IU) vitamin D per 100 ml so babies will require a vitamin D supplement until they are on sufficient volumes of formula. However, it is likely that activated vitamin D will be necessary to control the PTH. Levels of PTH that are below two times the upper limit of normal have been correlated with better growth and less signs and symptoms of bone disease in older children but there is no specific data for infancy [55].

Further details on CKD-MBD management are provided in ▶ Chap. 72, "Chronic Kidney Disease – Mineral and Bone Disorder (CKD-MBD)."

Long-Term Outcomes

Patient Survival and Causes of Death

Historically, infants who initiated chronic dialysis were less likely to survive or successfully receive a kidney transplant compared with the older children on dialysis [8]. However, in recent years (since 2000–2002), survival of infants on chronic dialysis has improved markedly [9, 11, 15, 56]. Combined data from the ESPN/ERA-EDTA registry, the IPPN registry, ANZDATA, and Japanese RRT registries indicated an estimated 2-year survival of 81%, and 5-year survival of 76% in neonates who initiated chronic dialysis during the period of 2000–2011 [15]. Data from the NAPRTCS registry reported that overall survival at 3 years after chronic PD initiation was 78.6% and 84.6% among the neonates and older infants (>1 month of age) who were treated in the period of 2000–2012, respectively [9]. Another analysis of the USRDS registry reported that patient survival at 1 and 5 years was 86.8% and 74.6% for those who initiated chronic PD as neonates and 89.6% and 79.3% for those who did so as older infants in the 2000–2014 era [11]. Nevertheless, patient survival remains lowest for infants on dialysis compared to older children on dialysis [8, 9]. The leading causes of death for infants on dialysis were infection (24.0–35.6%) and cardiopulmonary disease (16.7–23.5%) [10, 11, 15, 16]. This poorer survival in infants on dialysis is associated with the higher frequency of infection including peritonitis on PD, primary kidney diseases including autosomal recessive polycystic kidney disease, and the presence of comorbid conditions [27, 36, 56–58].

Kidney Transplantation

The primary goal for infants who initiate chronic dialysis is kidney transplantation. The ESPN/ERA-EDTA registry reports that 70.2% of infants had received a kidney transplantation within 5 years after the initiation of chronic dialysis therapy [10]. The USRDS registry reports that the median age at kidney transplantation was 2.0 years (IQR 1.5–2.9 years) and time to transplantation was 1.8 years (IQR 1.2–2.6 years) for infants who initiated chronic dialysis in the 2000–2014 era [11]. Furthermore, a report from combined data from the ESPN/ERA-EDTA registry, IPPN registry, ANZDATA, and Japanese KRT registries showed that at 5 years, of 264 children who initiated KRT in the neonatal period between 2000 and 2011, 99 patients had received a kidney transplant after a median of 25 (95 Confidence Interval 12.1–53.9) months, and 4 patients had received two kidney transplants [15].

Neurocognitive Outcomes

Because infancy is a sensitive time period for rapid neurodevelopment, infants requiring chronic dialysis therapy represent a very high-risk patient population for poor neurocognitive outcomes. Historically, before 1980, 20 (87%) of 23 infants with CKD developed profound neurological abnormalities including developmental delay, microcephaly, hypotonia, seizures, and dyskinesia [59]. Since the mid-1980s, long-term neurocognitive outcomes of infants requiring chronic dialysis have substantially improved, due to aggressive nutrition using nasogastric tube feeding, the elimination of aluminum as a phosphate binder, the provision of dialysis therapy and subsequent kidney transplantation [60]. However, recently two reports, in which patients with comorbidities including development delay and/or neurological disorder were excluded from the studies, indicated that long-term neurocognitive outcomes of infants who initiated chronic dialysis remains suboptimal [61, 62]. For example, one study reported that the mean (SD) patients' full scale intelligence quotient (FSIQ) scores were 78 (16.1) at an average age of 11.1 years, which were significantly lower than those of sibling controls (mean 94, SD 18.9; $p < 0.03$) [62]. Another study reported that mean (SD) FSIQ scores were 85 (20) at a mean age of 56 months, which was significantly lower when compared to normative data ($p < 0.015$) [61]. Noteworthy, both studies suggested that a shorter time on dialysis was associated with better neurocognitive outcomes [61, 62]. Given this result, a shorter dialysis vintage and earlier kidney transplantation may improve long-term neurocognitive outcomes in children who initiated chronic dialysis during infancy. Besides, further improvement of infant dialysis therapy is still needed to maximize the child's potential.

Conclusion

Chronic dialysis therapy is safe and feasible in infants. Mortality data have improved in children on dialysis over the past few decades, but the highest mortality rates are seen in infants who need chronic dialysis during the first year of life. PD remains the modality of choice, although improvements in dialysis technique, including the recent availability of dialysis machines designed for infants, makes HD a possible option.

Abstract

"Adequate" dialysis is often defined as a minimum clinically acceptable dose, below which occurs an unacceptable risk of poor outcomes. The term "dialysis adequacy" has been used for several decades primarily based on the measurement of small solute clearance including urea and creatinine and the findings from landmark adult-based clinical trials. Unfortunately, there are limited outcome-based data with respect to pediatric dialysis adequacy. Consequently, adult experience and the associated target clearances have been frequently extrapolated to pediatric patients, even though this point remains a matter of controversy. Small solute clearance represents only one part of the effectiveness of dialysis depuration, which should also include the clearance of larger and/or protein-bound molecules that

play an important role in uremic toxicity and are more difficult to remove. Moreover, the dialysis prescription should be adjusted in order to maintain fluid balance and normal blood pressure. The achievement of dialysis adequacy should reflect measures that comprehensively aim to reduce child's morbidity and mortality and to maximize nutritional status, cardiovascular and bone health, growth, and patient/family health-related quality of life.

In this chapter, we discuss the tools that are available for estimating the dialysis dose delivered to pediatric patients treated with hemodialysis and peritoneal dialysis taking into account the specific metabolic, clinical, and rehabilitative needs related to differences of age, body size, residual renal function, nutritional status, and pubertal development. Formulae to estimate or calculate depuration targets are presented referring to pediatric metrics when available. Pediatric observational data related to dialysis adequacy as well as existing pediatric guidelines and recommendations are also reported.

Introduction

Adequacy of dialysis treatment was first analyzed in adult hemodialysis (HD) patients with studies focused on urea kinetics and small solute clearance. The resultant concept of "adequate" dialysis was created to define a minimum dialysis dose, below which a clinically unacceptable rate of negative outcomes might occur including patient hospitalization and mortality. The ability to define dialysis adequacy in children as associated with clinical outcomes has been hindered by the absence of large-scale, definitive outcome studies in pediatric HD and peritoneal dialysis (PD) populations due to issues including small sample sizes from pediatric centers and outcomes of interest that are more difficult to study (e.g., nutritional status, growth, cardiovascular health, health-related quality of life). Consequently, the extrapolation of the adult experience and the associated target clearances from guidelines to children became a matter of controversy.

Small solute clearance represents only one part of the effectiveness of dialysis depuration, which should also include the clearance of larger and/or protein-bound molecules that play an important role in uremic toxicity and are difficult to remove. Indeed, the achievement of dialysis adequacy should reflect measures that comprehensively aim to reduce child's morbidity and mortality and to maximize nutritional status, cardiovascular and bone health, growth, and patient/family health-related quality of life.

In this chapter, concepts surrounding dialysis adequacy and the process to achieve the abovementioned treatment targets in clinical practice will be discussed in the context of maintenance dialysis in the pediatric population.

Hemodialysis Adequacy

Overview

Since the landmark adult-based National Cooperative Dialysis Study (NCDS) conducted in the late 1970s, HD adequacy has been defined primarily by small solute clearance, and more specifically by the delivery of a minimum dose of urea clearance [1, 2]. Urea is an ideal representative marker of small solute clearance in HD due to its small molecular weight (60 Daltons), its ease of diffusion across extracorporeal dialysis membranes, and its relatively even distribution across total body water. Urea also represents a worthy nutrition marker as the amount of urea nitrogen generation in between HD sessions yields an estimate of dietary protein intake.

During the course of a HD session, there is an exponential decline of urea or blood urea nitrogen concentration [BUN] that follows first-order kinetics, which is a concentration-dependent process. In an intermittent HD schedule (e.g., thrice weekly), the [BUN] profile throughout the week follows a saw-tooth pattern as the post-dialysis [BUN] is typically reduced to a certain percentage of the pre-dialysis [BUN] and will then rise almost to the same level seen prior to the previous procedure. Early attempts to model adequacy from the NCDS were focused on the pre-dialysis [BUN] and the [BUN] time-averaged concentration (TAC) computed as the area under the saw-tooth curve divided by time [2]. Dialysis was thought to be "adequate" if the pre-dialysis or TAC BUN was appropriately low. However, low levels were also found to be associated with high mortality rates in select patients, likely from inadequate protein intake. Consequently, HD adequacy has evolved into metrics of urea removal utilizing pre and post dialysis [BUN] from a single HD session including urea reduction ratio, single pool Kt/V, equilibrated Kt/V, and standard Kt/V along with validated nutritional markers (normalized protein catabolic rate), all of which will be discussed in this chapter. Due to lack of both evidence and widespread use, machine estimated measures of HD adequacy including ionic dialysance and ultraviolet absorbance of spent dialysate will not be discussed.

Urea Removal Indices

Urea Reduction Ratio (URR)

The urea reduction ratio (URR) is a crude assessment of HD adequacy that can be obtained by noting the magnitude of the decrease in [BUN] during an HD session, usually expressed as a percentage of the pre-dialysis [BUN] [3]:

$URR = (C0 - C1)/C0$ *or* $URR = 1 - (C1/C0)$, where C0 is the pre-dialysis [BUN] and C1 is the post-dialysis [BUN] in mg/dL or mmol/L.

In order to reduce the risk of underestimating the post-dialysis [BUN] and overestimating the dose of dialysis due to access recirculation (AR), the post [BUN] sample should be obtained after slowing the blood flow to a rate at which AR is minimal (e.g., 50–100 ml/min) for approximately 15 seconds or by stopping the dialysate flow for three minutes before obtaining the sample [4].

In over 13,000 adult HD patients, URR <0.60 was independently associated with a higher risk of mortality, but URR has not been similarly studied in children [5]. The Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines recommend a minimum URR of 0.65 and a target URR of 0.70 to ensure one is consistently meeting the minimum threshold in 3×/week HD [4]. The main disadvantages of URR include not accounting for both volume contraction and the urea generated during an HD session.

Single-Pool Kt/V (spKt/V)

The term "single pool" assumes that dialysis is occurring in the context of a simple uniform urea space without consideration of disequilibrium between the patient's intracellular fluid (ICF) and extracellular fluid (ECF) compartments. Kt/V is a dimensionless ratio that represents the volume of blood cleared of urea ($K \times t$) divided by the urea distribution volume (V) during a single HD session. K is the dialyzer blood urea clearance (ml/min) at a specific dialysis blood pump flow rate, t is the duration of the HD session (min), and V is the distribution volume of urea (ml), which is close to total body water. Therefore, a Kt/V of 1 implies that the numerator (K x t), or the total volume of blood cleared of urea during HD, is equal to V. The fraction can be greater than 1 as the body water compartment can be dialyzed more than once during a single HD treatment. However, the amount of urea removed diminishes exponentially as the Kt/V is increased linearly. Figure 1 reveals the curvilinear relationship of URR and spKt/V.

The gold standard method of determining spKt/V is from urea kinetic modeling (UKM), an iterative mathematical model that requires specialized computer software or a programmable calculator (e.g., "Solute-Solver" at www.ureakinetics.org) and several variables from successive HD runs. Using pre- and post-dialysis [BUN] values, formal UKM solves for patient total body water (V, in mL) and interdialytic urea nitrogen generation (G, in mg/min). Values for V and G are then used to calculate Kt/V and the normalized protein catabolic rate (nPCR), which will be discussed later in the chapter.

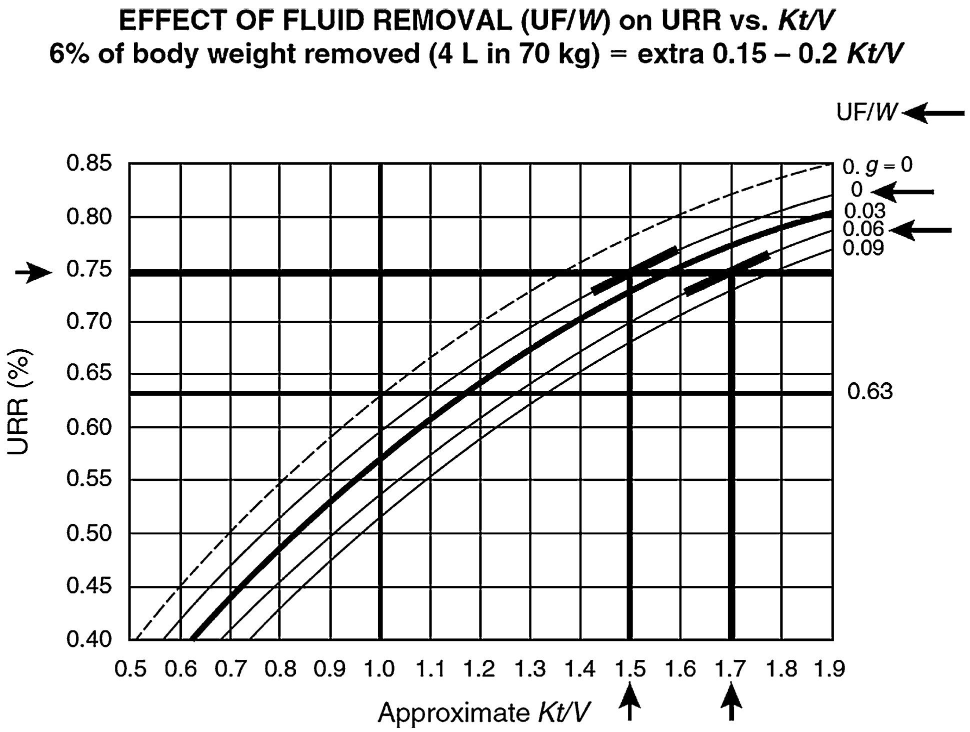

Fig. 1 Relationship of URR and Kt/V
Relationship between URR and Kt/V, taking into account urea generation and the effects of volume contraction (UF/W). Kt/V of 1.0 corresponds to URR (Urea reduction ratio) of 0.60 instead of 0.63 due to urea generation when there is no fluid removal. However, Kt/V of 1.0 can be attained with URR as low as 0.52 and average URR of 0.57 (heavy lined curve representing usual ultrafiltration of 3% of body weight). Similarly, URR of 75% can correspond to Kt/V of 1.5 in a patient with no fluid removal or to a Kt/V of 1.7 in patient from whom ultrafiltration is 6% of body weight. Reproduced with permission from Daugirdas JT. Handbook of Dialysis, fifth Edition. UF: Ultrafiltration (liters), W:Post dialysis body weight (kg), g: urea generation

As UKM is not routinely used in clinical practice, simpler spKt/V calculations are available based on its logarithmic relationship with the post- to pre-dialysis [BUN] ratio:

$spKt/V = -\ln(C1/C0)$ *or* $spKt/V = -\ln(1\text{-}URR)$, where ln is the natural logarithm, C1 is the post-dialysis [BUN], and C0 is the pre-dialysis [BUN] in mg/dL or mmol/L.

There are two variables that alter the relationship of URR and spKt/V not captured by the equation above. Figure 1 reveals that with increasing volume contraction represented from the different curves, a higher spKt/V is observed at any given level of URR. With fluid volume reduction, some urea is removed, but this removal is not associated with a change in urea concentration. Also when the small amount of urea generation that occurs during a dialysis session is factored into a standard 3.5 hour HD session, a Kt/V of 1.0 corresponds to a slightly lower URR of 0.60 instead of the expected 0.63 from the equation above. The Daugirdas II equation was developed to translate URR to spKt/V with adjustments for HD session length related urea generation and fractional volume removal [6]:

$spKt/V = -\ln(C1/C0 - 0.008 * t) + (4\text{–}3.5 * C1/C0) * 0.55\ UF/V$, where ln is the natural logarithm, C1 is post-dialysis [BUN], and C0 is pre-dialysis [BUN] in mg/dL or mmol/L, t is session length (hours), UF is volume of fluid removed during HD (liters), and V is the post-dialysis urea distribution volume (liters). V can be approximated as 0.55 x body weight (kg) or can be derived from pediatric anthropometric equations [7, 8], which will be further described in the PD adequacy section. The Daugirdas II formula has been shown to be a reliable alternative to formal UKM for spKt/V estimation in children of all sizes with <6% difference shown in paired data from 368 intermittent HD runs [9].

KDOQI recommends a minimum spKt/V of 1.2 and a target spKt/V of 1.4 for 3x/week HD [10]. A pediatric cross-sectional analysis from the United States (US) revealed that in 648 children receiving 3×/week HD, mean spKt/V was 1.6 with 89% achieving Kt/V $\geq$ 1.2 [11]. Observational data from US adolescents showed that older, larger, and African-American children are less likely to receive spKt/V $>$ 1.2 consistently [12].

Equilibrated Kt/V (eKt/V)

After dialysis is complete, urea diffuses back from the intra-cellular fluid (ICF) compartment of sequestered tissue sites to the patient's blood to cause a post-dialysis rebound phenomenon, which is largely complete by 30–60 min. Therefore, URR and spKt/V based on the typical sampling of [BUN] immediately after dialysis overestimates the true "equilibrated" clearance, known as eKt/V or double-pool Kt/V. Generally, eKt/V is approximately 0.2 Kt/V units lower than spKt/V in a standard 3–4 h HD session. However, the magnitude of urea rebound depends on the rate or intensity of HD given relative to body size and the degree of access recirculation. Four pediatric studies have revealed that the immediate post [BUN] rebounds by a mean of 17–25% to the equilibrated [BUN] at 50–60 min following HD [13, 14, 15, 16]. As it is impractical to have a patient wait for 1 h after HD to measure an equilibrated [BUN], many adult-based formulas have been devised to estimate eKt/V from spKt/V utilizing pre and post [BUN] obtained immediately after dialysis [17, 18, 19, 20].

A pediatric specific eKt/V equation has been validated by Goldstein and colleagues based on a logarithmic extrapolation of the rise of [BUN] in mg/dL from 30 sec to 15 min post HD to estimate the true equilibrated BUN (estBUN) [15, 16]:

$$estBUN = ([BUN_{15\,min} - BUN_{30\,sec}]/0.69) + BUN_{30\,sec}$$

The estBUN from this equation is then substituted for C1 in the Daugirdas II equation to obtain eKt/V. Compared to eKt/V from $[\mathrm{BUN}]_{50\mathrm{min}}$, this method has been shown to be the most accurate compared to other published eKt/V estimation methods utilizing $[\mathrm{BUN}]_{30\mathrm{sec}}$ [16]. However, the adult-based Daugirdas rate equation and Tattersall eKt/V equations utilizing $[\mathrm{BUN}]_{30\mathrm{sec}}$ also performed relatively well in children with a mean absolute difference of <5% from the true eKt/V [16]:

$eKt/V(Daugirdas) = spKt/V - 0.6 * (spKt/V)/t + 0.03$, where t is time in hours [20].

$eKt/V(Tattersall) = spKt/V \times t/(t + 35)$, where t is time in minutes [18].

Even though KDOQI has chosen not to recommend a minimum or target HD dose based on eKt/V, European best practice guidelines have set a minimum eKt/V threshold of 1.2 for 3×/week HD [21, 22]. A US-based study in children revealed that little difference in HD prescription management would result when comparing spKt/V versus estimated eKt/V values from the same HD treatment, justifying the use of spKt/V for adequacy assessments in children undergoing 3×/week HD [23].

Standard Kt/V (stdKt/V)

Increasing the frequency of HD alone increases dialysis efficiency while moving closer toward a more continuous pattern of clearance. The adequacy targets detailed above only apply to 3x/week HD, which has been the usual standard of care. With growing popularity of more frequent HD schedules, there has been a need to normalize and express the dose of dialysis independent of frequency and to reduce the delivered dose to a continuous equivalent weekly clearance. The stdKt/V concept suggests that therapies that achieve the same mean pre-treatment [BUN] are equivalent in delivered dose and therefore should achieve equivalent patient outcomes. This method was first developed by Gotch in 1998 and refined by Leypoldt in 2004 [24, 25]:

$StdKt/V = [168 * (1 - e^{-eKt/V})/t]/[(1 - e^{-eKt/V})/eKt/V)) + (168/(N * t)) - 1]$, where e is the exponential constant, t is time in hours, and N is the number of treatments/week.

eKt/V can be obtained with any of the known estimating equations utilizing spKt/V discussed previously, but none of these equations have been validated for therapies of arbitrary duration and frequency. Consequently, Leypoldt developed an equation to predict eKt/V for conventional HD, short daily HD, and daily hemofiltration therapy [25]:

$eKt/V = 0.924 * spKt/V - 0.395 * spKt/V/t + 0.056$, where t is time in hours.

The latest KDOQI update recommends for HD schedules other than thrice weekly, a target stdKt/V of 2.3 per week with a minimum delivered dose of 2.1 [26]. For pediatric 3x/week HD, Mammen and colleagues revealed that one should deliver a stdKt/V $\geq$ 2.0 in order to achieve spKt/V $\geq$ 1.2 and a stdKt/V $\geq$ 2.2 to ensure spKt/V $\geq$ 1.4 [27].

Issues of Scaling Dialysis Dose to "V"

As volume of distribution of urea (V) is closely tied to muscle mass, dosing dialysis by Kt/V may result in lower doses of dialysis for smaller patients, including women and children. Consequently, there has been some debate of whether dialysis dose should be scaled to body surface area versus V. In a study of children dialyzed 3x/week, a surface area normalized stdKt/V (SAN-stdKt/V) was significantly less in those younger than 10 years of age compared to adolescents [28]. With limited evidence and likely due to being a relatively new concept, KDOQI does not have any formal recommendations surrounding SAN-stdKt/V for adults or children at the current time.

Normalized Protein Catabolic Rate (nPCR)

Outside of small solute clearance, regular ongoing assessment of nutritional status is of utmost importance in an infant, child, or adult on dialysis. As traditional markers such as height, weight, and serum albumin are not always accurate indicators of nutritional status in children on maintenance HD, normalized protein catabolic rate (nPCR) has emerged as a useful and reliable tool. Normalized PCR, also referred to as the normalized protein equivalent of nitrogen appearance (nPNA), reflects the amount of protein in grams/kg/day that is catabolized in excess of the amount of protein that is synthesized. In a person who is in steady state (i.e., neither catabolic nor anabolic), the PCR reflects dietary protein intake. Therefore, an isolated nPCR can underestimate protein intake in a child with a significant growth spurt (anabolic state) and overestimate protein intake in a child on high doses of corticosteroids or suffering from a major infection (catabolic state). As it is difficult to directly measure protein intake, a method that is commonly used for estimation is to calculate the rate of increase in [BUN] between two hemodialysis treatments, otherwise known as G (mg/min). This can be obtained by formal UKM or can be reliably estimated from the difference of the pre and post [BUN] [29]:

$estG\ (mg/min) = [(C2 * V2) - (C1 * V1)]/t$, where C1 is post dialysis [BUN] in mg/dL, C2 is the pre dialysis [BUN] in mg/dL from the same session, V1 and V2 are the pre- and post-dialysis total body water values in dL respectively, and t is the interdialytic time in minutes.

Then nPCR can be calculated using the modified Borah equation [30]:

$nPCR\ (grams/kg/day) = 5.43 * estG/V1 + 0.17$, where V1 is the post-dialysis total body water as above.

Pediatric studies have demonstrated that in comparison to serum albumin, nPCR is a valuable nutrition marker in malnourished patients receiving intradialytic parenteral nutrition (IDPN), and that nPCR <1 gram/kg/day was predictive of persistent weight loss in adolescents [31–33]. Another study in children showed nPCR is overestimated slightly when using pre and post [BUN] from the same HD session compared to using the pre [BUN] from the subsequent HD session [34].

Residual Kidney Clearance

Although sometimes difficult to collect in children, regular assessment of residual urea clearance (Kru) through a timed hour urine collection in between HD sessions can be important to determine if the patient is meeting combined dialysis and residual kidney adequacy targets and is on the appropriate HD prescription. The Kru calculation is as follows:

Kru = ([UUN]/[BUN]) * urine flow rate (ml/min), where UUN is the urine urea nitrogen concentration and BUN is blood serum urea nitrogen concentration, often estimated from the average of pre- and post-dialysis [BUN] if the collection occurs during the entire interdialytic period. If the urine collection is 24 hours prior to dialysis in 3x/week HD, one can assume that the average [BUN] concentration during the collection is approximately 90% of the pre-dialysis [BUN].

The minimally adequate HD dose recommended by KDOQI is often given in the context of those with Kru greater than or less than 2 ml/min/1.73m^2. For those with Kru $\geq$2 ml/min/1.73m^2, the dose of dialysis may be reduced provided Kru is measured regularly to avoid inadequate dialysis, but this practice has not been adopted regularly by pediatric care providers. Kru can be combined with dialyzer urea clearance by converting it to a weekly clearance (Kru x 10,080/V) and adding it directly to stdKt/V. Daugirdas has also developed a stdKt/V equation that includes effects of fluid removal and Kru [35]. Kru of 3 ml/min is equivalent to a stdKt/V of approximately 1.0 per week. Inclusion of Kru is also advantageous because it allows for a more accurate measurement of G and nPCR, which are otherwise underestimated in patients with significant residual function. For an accurate nPCR, total urea nitrogen lost in the urine must be accounted for during the interdialytic period. With this measurement, the following term can be added to the calculated nPCR [36]:

> ([UUN] * 150) / (interdialytic interval (hours) × weight (kg)), where UUN is urine urea nitrogen in grams.

Is More HD Better?

Unfortunately, there are limited outcome-based data on pediatric HD adequacy due to several epidemiological barriers. Consequently, KDOQI recommendations surrounding pediatric HD adequacy including minimum delivered dialysis doses are mostly based on extrapolations from adult based studies. However, a pediatric section of the guidelines suggest that adequacy assessments should occur monthly and that children should receive at least the delivered HD dose as recommended for the adult population [4]. This is supported by an analysis of 613 US adolescents on 3x/week HD revealing spKt/V $<$ 1.2 was independently associated with a higher risk of hospitalization [37].

The landmark HEMO randomized study in adults dialyzed 3x/week found that increasing delivered doses higher than KDIGO recommended thresholds did not improve outcomes including mortality and hospitalization [38]. Whether these findings are generalizable to infants, children, and adolescents on HD is questionable considering that the relationship of dialysis dose to other important pediatric outcomes including growth, development, and quality of life is not well known. KDOQI states that considerations should be made to prescribe higher dialysis doses along with higher protein intakes in children who have greater nutritional needs to support growth and development [26]. This is based on pediatric observational data that suggests “more is better.” Tom and colleagues showed that growth was optimized with a target spKt/V $>$ 1.8 in 3×/week HD (5 h/session) and a high protein intake, even without the effects of growth hormone [39]. Equilibrated Kt/V $>$ 1.4 was also shown to be associated with improvements in inflammation status in 3x/week HD [40, 41].

More frequent HD and use of hemodiafiltration (HDF) has also been associated with improved outcomes in children. Fischbach and colleagues showed improved growth with HDF (5–6 sessions per week) and spKt/V $>$ 1.5 [42]. Goldstein and colleagues revealed that when switching from 3 to 6×/week HD, all children with nPCR $<$1 g/kg/day increased to $>$1.1 g/kg/day with stdKt/V $>$ 2.0 achieved in 85% of assessments [43]. However, the benefits seen in more frequent HD and HDF may not be related to small solute clearance and may be related to improved clearance of middle molecules, phosphate removal, as well as tighter fluid control leading to improved blood pressure and cardiovascular health. This is supported by a recent multicenter international study showing that despite similar Kt/V values, improvements in growth, blood pressure, interdialytic weight gain, and other cardiovascular measures were seen in children on HDF versus conventional hemodialysis [44]. This example nicely shows that although meeting adequacy targets for small solute clearance is important, several other domains of patient care adequacy are equally important for optimizing the care and quality of life of our maintenance HD patients.

Peritoneal Dialysis Adequacy

Overview

During the 1990s, the influence of small solute clearance on patient outcomes on peritoneal dialysis (PD) was a major focus of interest. Observational studies in adults on continuous ambulatory peritoneal dialysis (CAPD) suggested that improved patient survival and lower morbidity was associated with higher clearances of both urea and creatinine [45, 46]. As a consequence, small solute clearance was considered the key criterion of PD adequacy in clinical practice guidelines such as KDOQI [47]. Subsequently, a re-analysis of the landmark CANUSA study along with two other randomized controlled trials, including the ADEMEX study and another study from Hong Kong [46, 48, 49, 50], were unable to demonstrate any clear survival advantage with increases in peritoneal small solute clearance and showed that residual renal function (RRF) is a much stronger predictor of patient survival than urea and creatinine peritoneal clearance. Possible explanations for failure of increased PD dose to improve outcomes include higher intraperitoneal pressure associated with larger exchange volume, failure to increase clearance of middle molecules, and the consequences of increased exposure to glucose-based dialysate [51]. Moreover, the effect of the total fluid removal on mortality was not evaluated.

In children, even more so than in adults, adequacy of PD treatment cannot be exclusively defined by targets of solute and fluid removal [52]. Clinical assessment of adequacy of PD treatment should comprehensively take into consideration a series of clinical, metabolic and psychosocial aspects such as: electrolyte and acid-base balance; calcium and phosphate homeostasis; control of anemia; hydration status and blood pressure control; nutritional status and dietary intake of energy, proteins, salts, and trace elements; growth; psychomotor and mental development; level of psychosocial rehabilitation. Some of these issues which are more directly related to the delivered PD dose will be addressed in this part of the chapter.

Small Solute Clearance

In the absence of definitive outcome data in pediatrics to indicate that any measure of dialysis adequacy is predictive of well-being, morbidity, or mortality, 2006 KDOQI guidelines [53] stated that the target “delivered” small solute clearance in children should meet or exceed adult standards. These guidelines recommended the exclusive use of urea removal scaled for urea distribution volume (Kt/V_{urea}) for the evaluation of small solute clearance, with a total (peritoneal plus RRF) minimum target of Kt/V_{urea} of at least 1.7 per week. This recommendation was confirmed by pediatric PD guidelines published in 2020 [54]. Prior KDOQI guidelines [47, 55] also gave an opinion based recommendation for a minimum target of weekly creatinine clearance (CrCl) (Table 1) of 60, 63, and 66 Liters/1.73 m^2 for adults on CAPD, continuous cycling PD (CCPD), and nightly intermittent PD (NIPD) respectively, that took into account the continuous or intermittent regime of the three PD modalities, and were incorporated in pediatric European guidelines [56].

For practical reasons, peritoneal and RRF are usually added to determine total clearance, even if they may have a different impact on patient outcome. Some of the issues surrounding the evaluation of residual kidney clearance were addressed earlier in the HD adequacy section of this chapter. The term “delivered” refers to the actual dose the patient is receiving based on direct measurement of solute clearances and fluid removal, and not to an estimated value obtained by using a kinetic

Table 1 Peritoneal dialysis adequacy related formulae in children

Anthropometric total body water (TBW) prediction equations $^{(8)}$ Boys: $\text{TBW} = 0.10 \times (\text{Ht}*\text{Wt})^{0.68} - 0.37 \times \text{Wt}$ Girls: $\text{TBW} = 0.14 \times (\text{Ht}*\text{Wt})^{0.65} - 0.35 \times \text{Wt}$ Ht = height, cm; Wt = weight, kg
Body surface area (BSA) $^{\lceil}$ [60]$^{\rceil}$ $\text{BSA}\ (\text{m}^2) = 0.0235 \times \text{height (cm)}^{0.42246} \times \text{weight (kg)}^{0.51456}$
Protein nitrogen appearance (PNA) $^{(55,\ 61)}$ PNA (g/kg/day) = [(6.49 × UNA) + (0.294 × V) + protein loss (g/24-h)] / weight (kg) UNA = urea nitrogen appearance, resulting from 24-h urinary urea nitrogen (g) + 24- h dialysate urea nitrogen (g); V = urea distribution volume (L)
Kt/Vurea (per week) Kt/Vp (peritoneal) = (volume of dialysate (L 24 h) x DUN dialysate/ BUN plasma) × 7 / TBW (L) Kt/Vr (residual) = (volume of urine (L 24 h) × UUN urine/BUN plasma) × 7 / TBW (L) Kt/Vt (total) = Kt/Vp + Kt/Vr
Creatinine clearance (CrCl) (per week) CrClp (peritoneal) (L/week/1.73 m^2) = (24-hour D/P Cr x 24-hour dialysate volume in L) x 7 × 1.73 m^2 / BSA (m^2)

**CrClr (residual)(L/week/1.73 m^2) = 0.5 × [(24-h urine volume in L x urine Cr concentration /1440 min/day x serum Cr concentration) + (24-h urine volume in L x urine BUN concentration / 1440 min/day x serum Cr concentration)] × 1.73 m^2/BSA (m^2) × 7

CrClt (total) = CrClp + CrClr

**For peritoneal dialysis adequacy purposes, renal "CrCl" is the average of the urinary creatinine and urea clearances.

g = grams, h = hours, L = liters; BUN = blood urea nitrogen in mg/dL or mmol/L; DUN = dialysate urea nitrogen in mg/dL or mmol/L; UUN = urine urea nitrogen in mg/dL or mmol/L; D/P = dialysate to plasma solute concentration; Cr = creatinine in mg/dL or umol/L.

modeling program that are useful tools to improve the personalization of PD prescription, especially in APD patients [57, 58]. Assessment of the delivered PD dose is based on the measurement of dialytic and kidney clearance obtained through 24-hour dialysate and urine collection. All dialysate effluent produced for 24 hours should be collected, including daytime exchanges if performed. Total volume should be measured, and a small sample gathered after mixing the collected fluid thoroughly. Table 1 shows the formulae and calculation of weekly $\text{Kt/V}_{\text{urea}}$ and CrCl used for PD adequacy based on dialysate and blood samples. Compared to CAPD, NIPD patients may demonstrate variability in serum levels of urea depending on the time of the day of blood collection. When blood samples are obtained in the morning soon after completing a cycle of NIPD, dialysis adequacy as measured by Kt/V may be overestimated. Consequently, a mid-afternoon blood urea sample in NIPD may potentially be more accurate for determination of adequacy, even if difficult to obtain for practical reasons.

Solute clearance should be measured within the first month after initiating PD when full fill volume, scaled to patient's body surface area (BSA in m^2), and stable PD prescription have been achieved; thereafter, it should be measured at least once every six months if the patient is clinically well. More frequent measurements should be conducted when dialysis clearance may have been compromised (e.g., after repeated peritonitis episodes), when there has been a rapid decrease of RRF, or there is clinical suspicion of inadequate dialysis such as increased fatigue, decreased appetite, worsening fluid retention, and/or difficult to control hypertension. Moreover, if a patient is not doing well and has no other identifiable cause outside of uremia, a trial of increased dialysis is indicated.

Historically, both $\text{Kt/V}_{\text{urea}}$ and creatinine clearance (CrCl) have been employed to evaluate PD clearance. A discrepancy between urea and creatinine PD adequacy parameters has frequently been observed in adults and in children on APD [56], since urea clearance is more related to the total dialysate volume and the number of exchanges, while CrCl is predominantly affected by the dwell time (i.e., the duration of peritoneal membrane (PM) contact with dialysis fluid, also called "contact time") and by RRF. The finding of adequate Kt/V_{urea} values associated with inadequate CrCl values can be related to a hyperpermeable PM state or an insufficient intraperitoneal volume, since both are associated with a greater removal of urea than creatinine [59]. Finally, scaling of Kt/V_{urea} to body weight (BW) and CrCl to BSA may influence values obtained in infants and small children as a result of a higher BSA/BW ratio [56]. More recent recommendations suggest the determination of Kt/V_{urea} alone without CrCl for PD patients based upon the simplicity of its calculation, and because studies on adult PD patients did not provide evidence of a benefit in terms of patient outcome when expressing clearance in any manner other than Kt/V_{urea} [53, 54].

Kt/V_{urea} is normalized for urea distribution volume (V), which is assumed to equal total body water (TBW). Therefore, accurate estimation of TBW is a critical component of dialysis dose measurement. Since gold-standard isotope dilution techniques to determine TBW are laborious, costly, and not widely available, anthropometric prediction equations based on height and weight are commonly used to estimate TBW. Equations derived from healthy children [7] systematically overestimate TBW in pediatric patients receiving PD, and a new set of anthropometric TBW prediction equations have been developed in this patient population, and validated by comparison with the determination of TBW by means of heavy water (H_2O^{18} or D_2O) dilution technique [8]. These formulae are based on a new anthropometric parameter called *height times weight* that correlates linearly with TBW when both values are log-transformed and are reported in Table 1.

In conclusion, numerical targets of small solute clearance, as defined by currently available guidelines, should be interpreted cautiously and in the context of a thorough and repeated assessment of patient clinical and biochemical parameters. Whether the target clearances advocated for adults should serve as the standard for children remains an issue where evidence is scant.

Clearance of Middle-Sized Molecules and Phosphate

Failure to achieve adequate clearance of middle-sized molecules (300–5000 Daltons) and of phosphate is one possible explanation for the lacking effect of increased dialysis dose on improving patient survival [51]. In children, Shroff and colleagues found a correlation between serum phosphate levels and carotid intima-media thickness, a surrogate marker of cardiovascular disease [62]. Small solute and middle molecules clearances respond differently to changes in PD prescription. While the former is mainly determined by the frequency of exchanges and total dialysate volume, the latter depends more on the contact time between dialysate and the peritoneal membrane. Middle-sized molecules and phosphate removal is slow and equilibration with plasma levels only occurs with a long dwell such as the night dwell in CAPD or the daytime dwell in CCPD [63]. Removal of middle-sized molecules and low-molecular weight proteins, such as β_2-microglobulin and leptin, mainly depends on RRF [64, 65]. Moreover, an increasing restriction coefficient was reported for macromolecules with time on chronic PD, which is associated with increased size selectivity and a reduced peritoneal permeability for higher molecular weight solutes [66]. Hence, particular attention should be paid to middle-sized molecule clearance, especially in children on nightly intermittent PD, and as RRF declines. In order to increase the removal of middle molecules, a continuous PD regimen (CAPD or CCPD) can be adopted. Increased β_2-microglobulin and leptin clearance have been reported in patients receiving a long dwell with icodextrin solution [67].

The efficacy of phosphate elimination by a standard APD regimen is limited and independently predicted by total fluid turnover, the number of cycles, 2-hour dialysate-to-plasma (D/P) phosphate, dwell time, and ultrafiltration. It should be considered that while performing a peritoneal equilibration test (PET), the time needed to obtain a D/P for phosphate of 0.50–0.60 is three to four times longer than for urea. Schmitt and colleagues [68] raised the issue whether dialytic phosphate removal might provide a more reliable measure of dialysis efficacy than urea and creatinine clearance. By studying peritoneal phosphate kinetics and daily dialytic and renal phosphate elimination in children receiving APD, they found that 4-hour D/P phosphate and 24-hour phosphate clearance were lower in hyperphosphatemic children (3.38 +/− 1.17 vs 4.56 +/− 1.99 L/1.73 m^2/day, $p < 0.05$). Peritoneal transport state defined by the creatinine equilibration pattern poorly predicts daily phosphate clearances, suggesting that a specific evaluation of the D/P phosphate ratio could be done to define an individual's phosphate transport category. As overall PD phosphate clearance is limited, dietary counseling for phosphate intake restriction and phosphate binders use are needed to achieve the target of normal serum phosphate level that is associated with decreased risk of cardiovascular disease and better control of bone health [54].

Fluid Balance and Ultrafiltration

The PD prescription should be adjusted continuously to maintain fluid and sodium balance and normal blood pressure (BP). The North American Pediatric Renal Trials and Collaborative Studies [69] showed that 57% of nearly 4000 patients on dialysis had blood pressure values above the age-, sex-, and height-specific 95th percentile. The European Pediatric Renal Replacement Therapy Registry [70] reported systolic or diastolic BP standard deviation score (SDS) > 95th percentile irrespective of the use of medication in 35.5% of 851 pediatric PD patients. The International Pediatric Peritoneal Dialysis Network (IPPN) reported an overall prevalence of left ventricular hypertrophy (LVH) of 48.1% among 507 pediatric PD patients treated in 55 centers around the world and found that high total fluid output (urine plus PD-related UF) was protective from concentric LVH, especially in APD patients [71].

Routine evaluation of volume and sodium status, daily UF volume, and 24-hour urine volume is essential in the process of attaining adequate PD. A patient's extracellular volume is not easily measured and frequent assessment of patient "target weight" or "dry weight" mainly relies on clinical judgment. In clinical practice, the desirable target weight of a PD patient could be reasonably approximated to the weight at which the patient is free of edema and normotensive with minimal need for anti-hypertensive medications. Since fluctuations in patient weight secondary to growth and to changes in nutritional status may occur, reevaluation of target weight at each clinic visit is mandatory [54]. In addition to physical examination for edema, BP measurement and laboratory parameters estimating hemodilution (hemoglobin/hematocrit; serum albumin levels), volume assessment by means of bioimpedance spectroscopy has been proposed in children on dialysis [72]. Other volume assessment tools exist, such as measurement of circulating natriuretic peptide, lung ultrasound, inferior vena cava diameter, and collapsing index, but data on their use in children are limited.

Peritoneal membrane transport characteristics affect net fluid removal at a given dwell time by determining the osmotic gradient time curve of each individual patient. Patients with high or high average peritoneal transport are more at risk of developing fluid overload. A modification of the standard PET utilizing 4.25% dextrose solution can be employed to better evaluate UF kinetics and the maximum dip in D/P sodium, which reflects sodium-free water transport. If the patient has a high transport status, improved UF will be obtained by increasing fill volume as tolerated and/or shortening dwell time. In patients with decreased sodium-free water transport and no dip in D/P sodium after 1–2 h of the dwell, there will be no benefit from the use of a high dialysate glucose concentration. La Milia and colleagues [73] suggested calculation of the exact volume of free water transport by measuring the amount of sodium transported through the small pores over an 1-h dwell; since the total UF volume is known, subtracting the small pore transport from the total transport will give the amount of water transported through the aquaporin channels.

Any efforts should be maximized to employ the lowest possible glucose concentration required to achieve the desired UF rate to minimize glucose related toxicity. Further interventions to maintain patient fluid balance include:

- Dietary counseling on sodium and fluid restriction taking into account renal and/or dialysis-related sodium losses, since sodium depletion may result in hypotension and impaired growth, especially in infants.
- In children with RRF, use of loop diuretics and renin-angiotensin aldosterone system (RAAS) inhibitors (in patients who require antihypertensive medications, and with strict monitoring of potassium serum levels) [54].
- Evaluation of peritoneal transport characteristics by means of PET with subsequent adaptation of fill volume, dwell time, and PD solution tonicity.
- Use of icodextrin solution during a single prolonged dwell (daytime dwell in children on CCPD) with a fill volume above 550 ml/m^2 BSA seems to facilitate UF [74]; UF can be suboptimal in younger children due to a higher rate of icodextrin reabsorption [75].

- Adapted PD [76], combining short and long cycles in the same APD session, to optimize sodium and fluid removal (see PD chapter).

Clinical Correlates of PD Adequacy

Large-scale, Large scale, prospective studies in children on PD are lacking children are lacking owing to the small number of patients per center, and the relatively short period of time on dialysis prior to renal transplantation. Nevertheless, some pediatric observational studies effectively analyzed the relationship between PD dose and selected clinical aspects including growth and nutrition.

Growth is a potentially valuable outcome measure specific to pediatrics. Multivariable analysis from a multicenter study [57] showed a weak positive correlation of height standard deviation score (SDS) with dialytic creatinine clearance, and a negative correlation with peritoneal transport status. Children with a high transporter status were at increased risk of poor growth, which is difficult to explain. Growth rate is possibly more related to residual kidney solute clearance than to PD efficacy [77]. An IPPN study showed that in children treated with more biocompatible PD solutions with neutral pH and low glucose degradation products (GDP) content, growth was significantly better than in children using conventional PD fluids [78]. These data suggest that reducing inflammatory processes and carbonyl stress accomplished with reduced GDP exposure might improve growth rate.

In children on PD, dietary protein intake is only inconsistently correlated with delivered Kt/V_{urea} [79, 80, 81]. The relationship between Kt/V_{urea} and the protein equivalent of nitrogen appearance (PNA) calculated by means of the modified Borah equation utilizing timed dialysate and urine collection (Table 1) has often been criticized as merely being the result of mathematical coupling [61]. Finally, a higher Kt/V_{urea} was associated with a lower serum albumin level in children, suggesting that enhancing PD dose (i.e., to a $Kt/V_{urea} > 2.75$) may provide no further benefit, potentially owing to an increased loss of albumin into the dialysate [82]. However, in patients with high peritoneal transport and high $Kt/V_{urea,}$ serum albumin levels may be spuriously low in the presence of fluid overload due to poor UF and hemodilution effects.

The Role of Residual Renal Function

Prospective randomized trials of dialysis adequacy and observational studies in adult patients have confirmed that RRF is a much stronger predictor of patient survival than peritoneal clearance [48, 49, 50]. No data from large-scale trials on the relationship between RRF and patient outcome are available for children. However, an observational study reported higher growth velocity in children on PD with RRF compared to anuric children despite similar total solute clearance rates in both groups [77]. Other pediatric studies show that LVH is associated with a daily urine output of less than 0.5 L/m^2/day [71], and loss of RRF predicts diastolic dysfunction [83].

The rate of RRF decline in pediatric patients on PD was reported to be slower than in patients on HD, and high urine volume at the initiation of PD is predictive of sustained diuresis [84, 85]. Avoidance of excessive UF rates and of intradialytic hypotension, principally during HD, but also during PD sessions is recommended [86]. Studies of adult PD patients showed that low GDP fluids have the potential to better preserve RRF [87, 88, 89, 90]. However, multivariate analysis on 181 PD children attributed only a marginal increase of daily urine volume to the use of biocompatible solutions [86].

Preservation of RRF also includes avoiding nephrotoxic insults, such as exposure to nephrotoxic medications and radiocontrast agents, prompt resolution of volume depletion episodes, and prevention and early treatment of urinary tract infection. In PD patients, particular attention, including surveillance of serum drug levels, is required when aminoglycoside antibiotics are used to treat peritonitis in view of their nephro-, oto-, and vestibular toxicity, especially when repeated antibiotic course are required. Diuretic therapy can be used to increase urinary water and salt excretion and to delay the occurrence of oligoanuria [86]. Data from adult PD patients support the use of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) to slow RRF decline [91, 92]. Experience in pediatric PD patients is still limited. Data from the IPPN registry showed that the use of RAAS inhibitors tended to increase the risk of developing oligoanuria in a cohort of 401 incident PD pediatric patients [86]. In summary, interventions that may contribute to the preservation of RRF should be adopted whenever possible. RRF should be measured routinely by 24-h urine collection (Table 1) and PD prescription should be adjusted to its decline in a timely fashion, in order to prevent inadequate treatment.

Abstract

Kidney transplantation is considered a definitive modality of kidney replacement therapy. Living-related and preemptive renal transplantation is one of the crucial factors allowing planned and rapid access to optimal treatment. Given the worldwide shortage of kidney donors, the criteria for selecting suitable deceased donor kidneys must be carefully weighed up against the recipient's needs. Significant progress in immunologic testing and monitoring, as well as careful pretransplant evaluation of recipients and donors has improved the long-term outcomes of pediatric renal transplantation.

Kidney replacement therapy · Living-related kidney transplantation · Deceased-donor kidney transplantation · Recipient and donor evaluation · HLA matching · Donor-specific antibodies (DSA) · Graft survival · Graft nephrectomy

Introduction

Kidney transplantation in children is a relatively new field. While the first successful kidney transplants were carried out more than 50 years ago, renal transplantation in children in the 1970s was still rare and risky, and only with improved surgical techniques and better immunosuppression did numbers and outcomes begin to improve in the 1980s. Further improvements in graft survival and patient survival have occurred since 2000, possibly due to improved immunosuppression with the greater use of tacrolimus and mycophenolate, but this has plateaued more recently [1].

Many of the issues with kidney transplantation for children are the same as for adults, but concerns around graft quality, longevity, risk of infection, cancer, access to transplantation, and disease recurrence differ between these age groups.

As compared to adults with end-stage kidney disease (ESKD), most children are eligible for a kidney transplant, and in various jurisdictions receive priority for deceased donor organs. In the majority of countries, parents are a major source of kidney donation, with mothers being kidney donors more often than fathers, then extended family, and occasionally, altruistic donors. There has been an increasing use of deceased donor organs, and the vast majority of these are adult donors, although there is a growing desire to address the use of younger and even neonatal donors. Access to rapid and high-quality donation is of major importance for the lifetime outcomes of children with kidney failure. Full informed consent must be obtained from all donors, meeting recommendations of the Declaration of Istanbul [2, 3]. The pretransplant evaluation of children and donors is central to improved outcomes. In this chapter we discuss the workup of the recipient and of living and deceased donors.

Recipients

Renal transplantation is required in children with stage 5 chronic kidney disease (CKD), when glomerular filtration rate is maintained below 15 mL/min/1.73 m^2 and complications related to CKD become clinically overt. There can be a marked variation in uremic symptoms that patients show at different levels of glomerular filtration rate (GFR): some children demonstrate severe uremic symptoms even at GFR > 15 mL/min/1.73 m^2, while others remain asymptomatic even at much lower GFRs. The severity of clinical symptoms, like intractable hypertension, chronic fluid excess, metabolic derangements, acidosis, fatigue, poor energy levels and physical activity, and growth retardation must be considered in the decision to proceed with transplantation. The development of a pathway and checklist for potential donors and recipients will facilitate preemptive transplantation or placing the child on a deceased donor waiting list at the earliest opportunity [4, 5].

There is no universal age and body weight limit for recipients; however, renal transplantation in children below 10 kg is not common. Anatomical problems such as vessel diameter incompatibility, insufficient space in the retro/intraperitoneal area, and risk of renal graft hypoperfusion and thrombosis are major problems limiting the use of renal grafts from much older donors in minor recipients. The results of renal transplantation in children between 8 and 10 kg of body weight are, however, not inferior to older recipients [6, 7], but only performed in selected centers with relevant experience.

There are three distinct baseline clinical settings for renal transplantation. It may be performed before introduction of chronic dialysis, as a primary, preemptive form of kidney replacement therapy (KRT); in patients undergoing chronic dialysis; and as retransplantation in patients who have lost the function of a previous renal graft. In the first two settings, several aspects of the primary underlying kidney disease must be carefully evaluated in terms of the potential to modify management during or after transplantation. Patients with glomerular disease more often receive a transplant after a period of dialysis therapy, while children with nonglomerular disease more often receive a preemptive transplant. In cases of retransplantation, the clinical course of primary transplantation and the cause(s) of graft loss are more important for the outcome of the subsequent transplant [8].

Primary Disease and Renal Transplantation

One of the core assessments of candidates for renal transplantation is the risk to transplant outcome due to the primary disease. Congenital anomalies of the kidney and urinary tract (CAKUT) are the major causes of CKD in children. Lower urinary tract abnormalities can adversely affect the transplanted kidney, whereas isolated renal hypodysplasia has no real impact on transplant function. Glomerular diseases have the potential to recur after transplantation and persistent chronic glomerular injury frequently causes native proteinuria even in late CKD, as well as volume-independent hypertension. Ciliopathies affect surgical management due to the high urine output of native kidneys (as in polycystic kidney disease, in children, mainly recessive (ARPKD)) and may cause liver failure in some. Thrombotic microangiopathies (TMA) such as atypical hemolytic uremic syndrome (aHUS) may recur after transplantation and require disease-specific posttransplant management (long-term eculizumab prophylaxis or treatment). Metabolic diseases (like primary hyperoxaluria type 1) may cause severe extrarenal abnormalities and therefore may be an indication for liver-kidney transplantation, either as combined or sequential transplants. In all relevant cases, genetic testing should be performed before transplantation, with special regard to genetically determined rare diseases, which have the potential to recur (such as TMA or some glomerular diseases), or are associated with risk of malignancy and warrant recipient nephrectomies (such as WT1), or may impact the selection of living-related donors.

Evaluation of Native Kidneys and Urinary Tract Before Transplantation

Imaging of the kidneys and urinary tract followed by a careful assessment of bladder function is required in children with an abnormal lower urinary tract such as those with CAKUT, bladder extrophy, neurogenic bladder, posterior urethral valves (PUV), severe vesicoureteral reflux (VUR) with recurrent urinary tract infections (UTI), and prune belly syndromes. Both the anatomy and the function of the lower urinary tract should be evaluated using ultrasonography (size of the native kidneys and presence/severity of hydronephrosis), voiding cystourethrogram (status of male urethra, VUR, post-void residual volume), urodynamic tests (bladder function), and urethrocystoscopy (in urethral stenosis). Patients must be carefully evaluated to determine those who will require intermittent self-catheterization, pretransplant bladder augmentation, transplant ureterostomy, pretransplant creation of cutaneous urinary conduit using the appendix (Mitrofanoff), or creation of an intestinal (Bricker) conduit (pre- or intra-transplantation surgery). Selection of surgical variants must be individualized and determined by local center experience [9–12]. Native (bilateral or unilateral) nephrectomy performed before or during transplantation is required in selected cases, including children with huge kidneys such as in ARPKD, those with significant polyuria, patients with confirmed WT1 mutations and risk of malignancy, patients with intractable high-grade native proteinuria despite CKD stage 5, children with recurrent UTIs, and children with malignant renovascular hypertension. Pretransplant anuria does not affect outcome. Evaluation of the native kidneys requires ultrasonography with Doppler technique and, in selected cases, CT angiography [13–16].

Vascular Evaluation

Pretransplant evaluation of major vessels (arterial and venous) aims to predict the risk of surgical complications and to plan the placement and vascular anastomoses of the renal graft. The history of pretransplant hemodialysis/hemodiafiltration with use of femoral vascular access, history of thrombotic events, and previous renal transplant(s) are important indications for vascular imaging, including ultrasonography (USG) with Doppler technique, CT angiography, and MR angiography [17, 18].

CKD-Related Comorbidities and Risk Factors

CKD patients develop several uremia-related comorbidities, which may impact the safety and clinical course of renal transplantation, and therefore should be evaluated carefully before listing for transplantation. A high incidence of pretransplant hypertension (HT) and left ventricle hypertrophy (LVH) in up to 70% of children on dialysis is reported. All patients should be evaluated for cardiovascular risk, with use of echocardiography (ECHO) and 24-hour ambulatory blood pressure monitoring. A chest X-ray performed directly prior to surgery serves as a baseline for further monitoring in the pediatric intensive care unit after surgery and general anesthesia. Certain conditions where there is a large abdominal volume that may compromise lung function may warrant a respiratory evaluation prior to surgery. Obese patients should be evaluated in regard to metabolic syndrome (anthropometric evaluation, cholesterol, glucose, and homeostatic model assessment of beta cell function and insulin resistance). The risk of posttransplant diabetes triggered by the use of tacrolimus and steroids can, at least partially, be predicted by metabolic assessment such as a glucose tolerance test before transplantation [19, 20]. Liver function tests should be evaluated routinely, and patients with a history of hepatitis and specific genetic ciliopathies with hepatic involvement require additional workup. This may include USG-Doppler with evaluation of cysts (if relevant) and hepatic blood flow, gastroscopy for esophageal varices, and fibroscan for liver fibrosis. Patients with a history of thrombotic events should be screened for coagulopathies and genetic causes of thrombophilia [21].

Viral status including hepatotropic viruses EBV and CMV should be screened. EBV-seronegativity is common in younger children, and a risk factor for posttransplant lymphoproliferative disease and may influence the selection of immunosuppression [22]. Ideally, children should be fully vaccinated before transplantation. Live vaccines (such as BCG, measles, and varicella) cannot be given in a child on immunosuppression, and measles and varicella can cause very severe illnesses in the immunosuppressed child. Two situations require special attention: one is unsuccessful vaccination against hepatitis B virus, with nonprotective level of antibodies, as immunity is important in this cohort who will have multiple blood tests, surgery, and possible exposure to blood products; and the second is anti-meningococcal immunization, using the most broad spectrum vaccine available in patients who are likely to receive eculizumab prophylaxis or treatment [23, 24]. In children with previous malignancies, the timing and nature of oncologic workup is directed by their underlying condition; however, in general, transplantation is rarely performed until 18 months to 2 years have elapsed after complete remission of the malignancy [25]. Other non-CKD-related comorbidities involving vital organs should be individually analyzed. Irreversible non-renal organ failure may be an indication of multiorgan transplantation (liver-kidney, heart-kidney) and need distinct multidisciplinary assessment. In children with a progressive or life-limiting diseases, especially involving neurologic, metabolic, or mitochondrial cytopathic disorders with poor life expectancy or a very poor quality of life, patients should not be transplanted. This situation needs multidisciplinary assessment and decision-making between the parents and the wider medical team.

Retransplantation

Evaluation of a patient awaiting retransplantation is related mainly to primary graft loss. Recurrence of primary disease such as focal segmental glomerulosclerosis (FSGS) as the reason for graft dysfunction predicts the risk of recurrence in subsequent grafts and may impact the decision for selecting living-related or deceased donor transplantation. In patients with antibody-mediated rejection and graft failure, the severity of HLA sensitization must be evaluated with the mean fluorescence intensity of donor-specific antibodies (DSA).

Patients who require retransplantation should also be evaluated in terms of an indication for graft nephrectomy (versus leaving a graft in situ), preemptive subsequent transplantation, or return to dialysis before retransplantation. In sensitized patients without heavy proteinuria, graft nephrectomy may be contraindicated, as removal of the previous transplant may increase the level of circulating DSA [26, 27]; however, in patients with intractable proteinuria or in cases of graft loss due to BKV nephropathy (when the non-functioning graft may be the source of Polyoma BK virus), the benefit of graft nephrectomy may need to be carefully weighed up against the need for continued immunosuppression. Leaving the previous graft in situ may also pose a challenge for subsequent surgery [28, 29] (Table 1).

Living Donors

Living kidney donation provides one of the two possible organ sources in renal transplantation. It consists of donation of one kidney from a healthy donor benefiting a patient in ESKD. When donation occurs in a child from a parent or close relative, “free and informed” consent from the donor without any monetary incentive or coercion must be confirmed. The donor must be fully informed of and comprehend the risks associated with kidney donation surgery and of those that may occur during the long-term follow-up [30]. This is not a hurdle to the donation itself, but must be considered when psychological evaluation is performed, because the refusal of such a motivated donor may also be associated with negative effects. However, although the emotional link may lead the potential donor to accept greater risks, but donation should not be allowed if there are immediate or long-term medical risks to the donor [30]. This is a responsibility of the transplant center that must make the final decision.

Living kidney transplant offers several advantages for the recipient and may be performed during the final stages of chronic renal insufficiency, even before the need for dialysis is established. This has been demonstrated to be an advantage for the child: dialysis in children may impair cognitive function, growth, bone mineral regulation, cardiovascular disease, and overall life span, compared with transplantation [31]. Moreover, long-term dialysis may also negatively impact on graft and patient survival [31]. An early transplant, as guaranteed by the availability of an organ from a living donor, is therefore highly

Table 1 Evaluation of pediatric candidates for renal transplantation

Indications	Tests and evaluations	Who should be evaluated
Specificity of primary renal disease – cause of CKD	Relevant to disease Genetic, wherever relevant	All cases
Urologic	USG Voiding cystourethrogram Urethrocystoscopy Urodynamic tests	All cases require USG Urethra obstruction History of bladder dysfunction Recurrent UTIs
Vascular	Ultrasound-Doppler CT angiography (of major and renal vessels)	All cases In small(er) children or those with known abdominal pathology
Cardiovascular risk	Echocardiogram Ambulatory BP monitoring Chest X-ray Workup for metabolic syndrome	All cases
Liver tests	Tests for liver function Viral status (hepatitis B, C, and HIV) Gastroscopy Fibroscan	All cases All cases Ciliopathies and chronic liver diseases
Coagulation system	Coagulation panel Genetic screening	Patients with history or risk of thrombotic events or thrombophilia
Oncologic workup	Specific for type of malignancy	Patients with known malignancy
Retransplantation	Sensitization tests: Mean fluorescence intensity (MFI) to donor-specific antibodies (DSA) BKV status	All cases Patients with BK virus nephropathy

desirable for a child in ESKD. The risks to the donor, who is a healthy subject and does not need to have a kidney removed, must be carefully considered, keeping in mind the guiding principle "first do no harm." By donating the kidney, a donor has a small risk of perioperatively death (0.03%, in a large retrospective registry study in the USA of more than 80,000 live kidney donors between April 1, 1994 and March 31, 2009.) [32]. Also, after a longer follow-up (median 15 years), the risk of death for former donors is higher: the hazard ratio for all-cause death is 1.30 [33]. It is mandatory that transplant centers offer an optimal surgical technique, associated with the best outcome in terms of complications and optimal recovery [34]. This requires that the surgeon is well trained in "mini-open" laparoscopy or hand-assisted laparoscopy, which are currently considered the techniques associated with the best outcome [34]. Risk of developing ESKD is not high, yet it is increased when donors are matched with "healthy" non-donors [33, 35], even though absolute numbers remain small. Renal function before donation should be checked carefully, by means of one or more reliable methods: measured creatinine clearance or measured GFR using an exogenous filtration marker (such as inulin, iothalamate, 51Cr-EDTA, iohexol, and 99mTc-DTPA [34, 36]), and patients with a GFR below 60 ml/min/1.73 m^2 should be excluded from donation [34, 36]. In this context, age becomes an important parameter: a mild reduction of renal function in a 60-year-old man is not as significant as in a younger potential donor [37]. Age, thus, becomes a variable to be always included in the evaluation process. This applies to several other issues that may be a cause for late complications, such as renal stones or hypertension. For the latter, for instance, the 2017 KDIGO guidelines suggest accepting a donor who shows blood pressure below 140/90 on treatment with one or two antihypertensive agents [38]. However, even acknowledging the absence of large studies, some papers have showed that blood pressure after kidney donation increases more than normally expected with aging [39, 40]. The development of hypertension is therefore possible over time in a young donor. Even well-controlled hypertension in a young donor probably requires additional caution. This may also apply to other parameters (e.g., proteinuria): detection in a young candidate is more alarming than in an older donor. Classically, older donors rather than young age have been a concern for organ allocation in children. However, most guidelines [34, 36, 41] do not consider older age itself as a cause for excluding a potential organ donor. We should not consider age to be an exclusion criterion per se. The donor should always be fully evaluated, and age is only one of the parameters to be included in the general assessment. A comprehensive list of tests needed to evaluate the suitability of a donor is available and is regularly updated in all existing guidelines [34].

The most recent KDIGO guidelines have proposed a new approach to donor evaluation, based on an "integrative risk-based approach" [34]. This means that, even in the absence of a single clear contraindication, the association of several "negative" parameters might prompt a transplant center to consider excluding a donor. This would be a step forward to improving the long-term outcome of potential kidney donors, but the importance given to each assessment criterion needs to be carefully considered [37, 38]. A young candidate may appear to be a perfect donor just because he has not yet had the time to develop clinical problems, but these may occur over time. This is even more important in a pediatric setting, where young parents of young children, therefore, with a long life expectancy, are being considered as potential donors. The use of risk equations to predict the risk of ESRD in a candidate for kidney donation is recommended [34], but their long-term reliability is still to be demonstrated [42]. It is also important to consider that these predictive methods may be reliable only for the population in which they have been estimated, as significant differences may apply from one population to another [42].

Genetics

Diseases transmitted by means of genetic mutations: Alport syndrome, autosomal dominant polycystic kidney disease (ADPKD), PAX2-mediated CAKUT, and, less frequently, others such as Dent, Frasier, and Gordon syndromes are often encountered in the clinic. In all these cases, the mutation is also present in the parents of the child [40]. In dominant disorders, such as ADPKD or in the X-linked diseases, as in Alport syndrome, the causative mutation must be excluded in the potential donor, whereas, in recessive disorders, usually the candidate donor can be accepted [41, 43]. However, it is always necessary to consider genetic screening and counseling before a final decision is taken. Two diseases, however, deserve some further consideration. In aHUS, a well-known cause for renal failure in children, all efforts should be made to ascertain the mutation in the recipient and in the candidate donor [24]. Transplantation can only be performed if the mutation found in the recipient has an indisputable role in the pathogenesis of aHUS and is not found in the donor [24]. FSGS may occur as a genetic or sporadic form [44]. In the genetic form, parents are obligate carriers and are usually considered as suitable donors, even if, as pointed out by several authors, there is an increased risk for the parents of children with podocin mutations, which is present in combination with the common R229Q variant, which has an allele frequency of 3.7% in the general population. This polymorphism may, in fact, induce a minimal increase of developing a late-onset nephrotic syndrome [45]. This variant should, therefore, be screened before allowing a kidney donation, and, in the case of positivity, the opportunity and the risk of allowing the donation should be carefully discussed with the candidate. In the sporadic forms, no risk for the donor is present; however, a possible relapse may be expected in almost one-third of the patients [44], and, if a first transplant is lost due to relapse, the risk for a new failure becomes much higher [46]. Most of the existing guidelines do not exclude LRD in children with FSGS in the first transplant, whereas a second transplant should be allowed only in specific conditions [34, 38, 47]. More recently, the importance of the risk associated with the presence of variants of the APOL1 alleles has been highlighted. However, the meaning of analyzing these risk variants is still unclear. They are common in persons of sub-Saharan African descent. Approximately 13%

of African Americans carry two APOL1 risk alleles. This condition increases the risk of FSGS, proteinuria, reduced GFR, younger age on dialysis, and more rapid progression of kidney disease [34, 38]. The presence of two APOL1 risk alleles in a deceased donor associates with two to four times higher RR of graft loss in the recipient, compared with 0 or 1 risk alleles [34, 48]. There is currently not enough information to suggest a definite plan for this issue, and a large study has just been launched to ascertain the actual importance of this phenomenon [49].

ABO Incompatible

A possible hurdle in the search for a compatible donor is the ABO-incompatibility between the candidate for transplantation and the potential donor. In these cases, two options exist: ABO-incompatible kidney transplant or paired kidney donation (crossover transplantation). The first option is widely used in the adult setting with excellent results, although still inferior to ABO-compatible control patients [50]. Even if results are considered satisfactory, there is still excess mortality and loss of kidney grafts compared with ABO-compatible transplants within the first 3 years after transplantation [51], and a risk from increased immunosuppression. In children, good results are reported [52] but the procedure is more invasive than that needed for compatible transplantations, as the ABO-incompatible desensitization protocols require preemptive removal of isoagglutinin by means of plasmapheresis or immunoadsorption, and specific conditioning protocols, which most often include anti-CD20 agents [51]. The alternative is paired kidney exchange, where two noncompatible donors swap their kidneys in order to let both their candidates receive the organ. This may be done as a direct donation between two couples or after longer chains of donors/candidates. The efficacy of this practice mainly depends on the dimension of the donor's pool, thus nationwide programs are desirable [53], but programs involving more than one country have also been proposed [54]. Moreover, it is important that this system considers a possible rescue system for the transplantations that show a primary nonfunction, in order to increase the willingness of patients to participate. Several systems guarantee the prioritization of an organ allocation in a future end chain or from the deceased donor waiting list in case of early failure [53, 55].

Posttransplant Monitoring of the Donor

It is important that post-donation monitoring is the responsibility of the transplant team [34, 38], which should guarantee at least a yearly monitoring of renal function and blood pressure. Also, it is important to stress the need for each former donor to implement healthy lifestyle behaviors [34]. A pediatric center might also decide to associate with an adult nephrology center for donor monitoring for logistic reasons.

The Deceased Donor

Pediatric Placement on a Deceased Donor List

Most children, as compared to adults with ESKD, are listed for transplantation. The placement of a child on a kidney donor list varies across countries. In most countries the allocation of deceased kidneys is governed by a state or national allocation group. In some cases, this is a nongovernment body, such as the USA, where this is contracted out to United Network for Organ Sharing (UNOS). Donors may be either brain dead or have suffered cardiac death. The definition of these is closely regulated in most jurisdictions. Consent to donate varies in different countries, with some having an “opt-in” system, requiring evidence of prior intent to donate or consent from relatives; however, in other countries, an “opt-out” system exists. The relative benefits and ethical principles underlying each model remain a subject of continued discussion.

Donor lists are created using blood group and mostly comprise waiting time on dialysis and closeness of HLA matching between the recipient and the kidney donor. For highly matched kidneys where the two major Class I alleles A and B and the major Class II allele have a 6 out of 6 match, many jurisdictions will give priority for allocation of that "full" match in their jurisdiction and may also give it priority nationally or across national boundaries in places such as Europe.

Blood Group Issues

Historically, kidneys were thought to only be able to be given to recipients who did not carry antibodies to the blood group of the donor kidney. This meant that blood group O kidneys could be donated to all other blood groups and their own, whereas AB kidneys could only be given to patients who were blood group AB. Given this situation, most allocation for deceased kidneys is done within blood groups.

ABO mismatched transplantation has been discussed in the living donor section, and, although theoretically possible, ABO incompatible deceased donors are rarely used for pediatric recipients [52].

Immune Matching

As well as waiting time, most centers give importance to the degree of immune matching between donor and recipient on the deceased donor waiting list. Long-term data shows that HLA identical kidneys do best, and that survival of donor kidneys becomes progressively worse with worse matching [54]. Further Class II matching is probably more important than Class I matching. Increasingly, specific antigenic peptides on the surface of HLA molecules, called eplets, are being evaluated as they potentially give a better risk score than the HLA mismatches alone [56, 57]. Historically, HLA testing was done using recipient sera to screen for anti-donor antibodies and measurement of the HLA on the donor kidneys. Donor and recipient HLA typing is now done by rapid molecular methods by virtual cross-match using flow cytometry with HLA-antigen-specific beads. This allows identification prior to acceptance of a donor or the presence of donor-specific antibodies, where the amount of antibody is measured by the mean fluorescence intensity of antibodies binding to the beads. For two reasons, the degree of matching is less of a component in allocation than it was initially thought. The first is the issue of equity, where patients from rare ethnic groups would wait longer because of greater mismatches with the pool of donors. The second is the improvement in immunosuppression, reducing the risk of rejection, even in mismatched grafts [58].

Quality of the Kidney from the Deceased Donor Pool

As well as immune matching, a number of factors relating to the quality of the kidney from the donor waiting list must be considered. The most commonly assessed factors can be considered from the kidney donor profile index that combines a number of donor factors into a single number that summarizes the likelihood of graft failure from a deceased donor. This is dominated by the age of the donor, but includes a number of infectious and vascular risks. The greater the age difference between donor and recipient, the worse the outcome [59]. Genetic factors may also predict a transplant kidney's risk of developing graft fibrosis [60]. The degree of acute kidney injury and delayed graft function can have a significant effect on patient and graft survival [61].

Infectious Risk

Potential pathogens, including Hepatitis B, Hepatitis C, and HIV, are a serious risk to the recipient and must be screened for using both serology and rapid molecular diagnostics. In addition, the donor's CMV and EBV serological status should be determined. The presence of a CMV-positive kidney will require prophylaxis and/or treatment with antiviral agents such as valganciclovir or valcyclovir for 6–12 months [62]. EBV-positive kidneys carry the risk of both EBV-related disease and the future development of PTLD and even lymphoma [63]. The presence of either of these viruses or of the BK virus requires close monitoring and appropriate treatment for the recipient [64].

Marginal Donors

To enlarge the donor pool, "marginal donors" are being used. These includes non-heart-beating donors or donation after cardiac death, older donors, and very young donors, including "en bloc" donation [65]. Other areas of higher risk include donations from patients with certain malignancies, or donor kidneys with a resectable tumor [66]. Infectious risk is an area which has become greater with the increasing number of opioid-dependent donors [67]. These donors have a risk of blood-borne viruses, including HIV and Hepatitis C. In many cases, the risk is quantifiable and low, but recipients (and/or their legal representatives) must be fully informed of the associated risks and appropriate consent taken.

Currently, it is not possible to perform any manipulations on a donor kidney prior to the cessation of the donor's life. A major intervention that has been applied is the use of cold, and, more recently, warm pulsatile perfusion to support a kidney prior to transplantation and possibly to improve its function. Pharmacological manipulation of the kidney to improve graft life and function may also be possible [68]. Of particular interest is the smaller donor. Smaller children on dialysis may do better in the long term with a smaller kidney that allows earlier transplantation. There is early tantalizing data that smaller kidneys may have the capacity to grow with their recipient [69]. However, the risk of graft thrombosis in the small kidneys must be balanced against the benefits of earlier transplantation, and these transplants can only be performed in centers with the requisite surgical and medical expertise.

Equity Versus Utility

As a precious resource, there is significant pressure to maximize the years off dialysis provided by a donor kidney. This is balanced by the need to have equitable access for recipients, regardless of race, sex, or socioeconomic status. Pediatric recipients may have additional comorbidities such as blindness, as well as cognitive or physical disabilities, where access to a kidney transplant requires advocacy from their team [70].

Looking After Children

In many countries preference is given to children over adults on the kidney transplant waiting list, prioritizing them either at the commencement of dialysis or after a period of time on dialysis [71]. In some, this is by giving children the equivalent time on dialysis to move them up the list; in other areas, it is by offering them younger or better matched kidneys – in some cases, trying to match for HLA Class II because of better potential long-term outcomes associated with this [72]. The definition of "pediatric" recipients varies between jurisdictions, with some giving preference to 15 and below and some to 18 and below. Increasingly, there is a desire to also consider some advantage for young adults who may have a similar justification for access to a transplant.

Determining the Suitability of a Deceased Donor Kidney for a Particular Recipient

For most children, the decision around a potential donor will involve a nephrologist and a transplant surgeon weighing up the quality of a particular donor against the potential risks. In general, most physicians will receive a large amount of data on the donor, including infectious risks, HLA matching, the presence of DSAs, and associated morbidities of the donor, such as weight, hypertension, diabetes risk, smoking, kidney function, appearance of the kidneys, and vascular information such as the number of vessels and the presence of CMV, EBV, and other infectious agents [73]. Once a decision to go ahead is made, the coordination of a retrieval team including clinicians, surgeons, intensivists, and nursing and allied health workers is required for the fastest possible transport of the kidney to the recipient. There are many models that are successful, but high volume, ongoing review, and expertise of the retrieval team are often the basis for the best outcomes [74].

Multiorgan Transplants

Multiorgan transplants require a multidisciplinary team approach to coordinate the decision about appropriateness and timing of surgery. The listing for combined organs for children generally involves the need for a larger pool of potential donors and agreement for the use of combined organs to be prioritized over individual use. In both ciliopathies and certain metabolic diseases, multiorgan transplants have improved patient survival and quality of life [75–77].

Summary

Pediatric recipients of kidney transplants are a special group, with unique recipient- and donor-related issues. Improving transplant outcomes depends on a careful evaluation of the pediatric recipient and their potential donor in order to improve the quality of life and life expectancy to these children.

Abstract

Kidney transplant is the treatment of choice for children with end-stage kidney disease due to the beneficial effects on growth and development. Fundamental to the success of the transplant procedure is the close collaboration among multiple disciplines including transplant surgery, transplant anesthesia, pediatric intensivists, and transplant nephrology. Awareness of the key surgical and urologic issues as well as the potential complications helps guide early posttransplant management in order to optimize outcomes.

the pediatric recipient. The young pediatric recipient may be especially vulnerable to transplant complications emphasizing the necessity of meticulous surgical technique and attentive post-transplant management [1, 2].

In this chapter, we discuss the surgical and urologic procedures used in pediatric kidney transplantation. In addition, hemodynamics, perioperative fluid and electrolyte management, anticoagulation, and strategies for infection prevention are discussed. Also, postoperative complications such as graft thrombosis, renal artery stenosis, lymphoceles, as well as urologic obstruction or leakage are highlighted.

Surgical Management

Back-Table Preparation of the Donor Kidney

The anatomic structures transplanted during deceased donor kidney grafting are composed of the kidney with perinephric fat, the renal artery with a cuff of the donor aorta (Carrel patch), the renal vein with a cuff of the inferior vena cava, and the ureter with periureteral tissue. The kidney which is first flushed with iced preservation solution is then immersed in an iced solution (such as saline, Ringer's lactate or histidine-tryptophan-ketoglutarate solution) to prevent warm ischemia. Perinephric fat is removed in the course of back-table preparation. In the event of multiple vessels, reconstruction may be required prior to grafting. Whereas a small upper pole vein may be ligated owing to a sufficient collateral venous drainage, the whole arterial supply must be revascularized in the absence of a collateral arterial circulation of the kidney. Careful handling of the ureter and periureteral tissue is of vital importance to avoid inferior blood supply to the ureter and subsequent ureteral necrosis. In the case of living donation, the donor artery and vein are shorter because the vena cava and aorta are obviously unavailable [3].

Operative Technique in Older Children and Adolescents

The transplantation procedure for children weighing more than 20 kg is usually the same as that for adults. The pediatric patient is brought to the operating room to receive general anesthesia and a central venous line is placed. If there is a concern that delayed graft function may occur, a double-lumen central venous line suitable for postoperative hemodialysis should be placed. An additional arterial line can be placed percutaneously if invasive blood pressure measurement is required for hemodynamic monitoring in an unstable circulatory situation. The patient is put into supine position and a urethral catheter is placed. The bladder is irrigated and distended with sterile saline [4, 5].

In contrast to other transplant organs, the kidney is placed heterotopically, usually retroperitoneally in the right iliac fossa because of the more superficial and horizontal course of the right iliac vein. However, some surgeons favor transplanting the kidney contralaterally, which means placing the right kidney in the left iliac fossa and vice versa, whereas others prefer placing the kidney ipsilaterally. Of course, pretransplant surgeries, multiple transplants, and nephrectomy of the native kidney must be taken into consideration when choosing the transplant bed.

Occasionally, native nephrectomy is needed at the time of transplant. Indications for nephrectomy include (i) need for space in small children or in the setting of enlarged kidneys such as polycystic kidney disease; (ii) uncontrolled renal related hypertension; (iii) recurrent infections in native kidneys; (iv) polyuria; and (v) nephrotic syndrome. Native nephrectomy is often needed in patients with active nephrotic syndrome, either congenital or acquired. It is suggested that native nephrectomies are performed prior to transplant in order to allow time for the hypercoagulable physiology to correct to minimize the risk of vascular thrombosis [6]. In some centers, a unilateral nephrectomy is performed months to years before transplantation, with the second kidney removed at the time of the transplant surgery while in others, both are removed prior to transplant.

The typical incision is a modified lower abdominal hockey-stick type, with minimal muscle-splitting, or like the so-called Gibson incision, which extends from the midline above the symphysis pubis in curvilinear fashion to a point two finger-breadths medial to the anterior superior iliac. The inferior epigastric vessels and lymphatics are ligated and divided, and exposure of the iliac fossa is obtained by reflecting the peritoneum medially. In males, the spermatic cord is preserved, and in females, the round ligament is divided. By placement of a stationary retractor, the external iliac and common iliac vessels are exposed and dissected. It is left to the surgeon's discretion to perform heparinization in close cooperation with the anesthesiologist. The renal vein is usually anastomosed first, to avoid insufficient perfusion of the lower extremity. After placement of vascular occlusion clamps, the venous anastomosis is performed between renal donor vein and recipient external or common iliac vein in an end-to-side fashion using a running 5–0 or 6–0 polypropylene suture. The arterial anastomosis is usually done between the donor renal artery and the recipient external or common iliac artery in an end-to-side mode using a running 5–0 or 6–0 polypropylene suture. The arterial orifice can be facilitated by means of a cardiac punch. In case of multiple renal arteries, an aortic Carrel patch or side-to-side anastomosis of equalized renal arteries may be needed. To promote diuresis, mannitol and furosemide are usually administered intravenously. Before reperfusion of the transplant kidney, it is essential to establish sufficiently high systolic blood and central venous pressures. Upon completion of the anastomoses, the vascular clamps are removed. Hemostasis should be ascertained by examining the anastomoses, capsule, and hilar fat. Attention then has to be focused on the ureter [3, 5]. Urinary continuity may be restored by different techniques which will be discussed below (see subchapter "Urologic Management").

Surgical Considerations in Young Children and Small Infants

In children weighing 10–20 kg, an extraperitoneal approach is still feasible, but anastomoses are usually done in an end-to-side fashion between renal vein and inferior vena cava or common iliac vein as well as between renal artery and aorta or common iliac artery. In small infants under 10 kg, most surgeons use an intra-abdominal approach. A midline longitudinal abdominal incision is performed extending from the xiphoid to the pubis. Cecum and ascending colon are reflected medially to expose the aorta and vena cava inferior. Aggressive volume replacement is necessary at the time of reperfusion since a large adult donor kidney claims a significant portion of the normal pediatric blood volume [4, 6–8].

Few transplant surgeons choose an extraperitoneal approach, even for small infants, to exclude bowel complications and to enable peritoneal dialysis after renal transplantation, if required, and an easier access to transplant biopsy. Vitola et al. reported on a study in 62 patients weighing less than 15 kg, in whom an extraperitoneal approach proved most successful [9]. Recently, Alameddine et al. presented a method where anterior mobilization of the recipient liver and kidney is accomplished through blunt dissection of the renal fossa. It allows sufficient space to be created for the adult renal allograft to lie retro-hepatically and to occupy the space from the diaphragm to the bladder. This method yielded excellent results in a single-center study in 21 pediatric patients [10]. A recent analysis of the *Cooperative European Paediatric Renal Transplant Initiative* (CERTAIN) registry evaluated the outcome of kidney transplantation in small infants. In that cohort, renal grafts from adult donors were transplanted only retroperitoneally with no increased risk of graft compression [11].

There are several reports of renal transplantation in infants weighing less than 10 kg [12–15]. Royo Gomes et al. studied the outcome of 10 kidney grafts in 9 infants weighing 7 kg on average [13]. All were placed retroperitoneally. Three of

10 grafts were lost; 2 due to acute rejection and recurrence of the primary renal disease, respectively; and 1 due to ischemia within the first 48 h. The authors concluded that kidney transplantation is feasible in low-weight patients despite technical difficulties. In addition, Singer et al. compared the outcomes of renal transplantation in 245 children weighing 8 to <10 kg with that of 804 patients weighing 10–13 kg [14]. They found no significant difference in graft survival between both groups [14]. Another single-center study showed similar patient and graft survival in renal transplant patients weighing <11 kg and those weighing >11 kg. Nevertheless, the authors emphasized the importance of aggressive fluid resuscitation and attention to perioperative hemodynamics to avoid graft thrombosis in very small children [15].

Urologic Management

Continuity of the urinary tract is usually achieved by neoureterocystostomy. The transplant ureter should be trimmed of devascularized tissue and tunneled under the cord structures without twisting. Use is made of different methods of neoureterocystostomy [3, 5, 6].

A common approach, termed Lich-Gregoir technique, consists in reimplanting the ureter extravesically into the bladder. This approach was originally intended for correction of vesicoureteral reflux and was introduced in kidney transplantation in 1968. The muscular layer of the bladder is divided to expose the bulging mucosa. Upon opening of the mucosa, an anastomosis is performed between the ureteral and bladder mucosa, a muscular tunnel of 2–3 cm length being closed over the mucosal anastomosis to prevent vesicoureteral reflux. Care has to be taken to avoid ureteral strangulation. The advantages offered by this extravesical approach are a smaller bladder cystostomy and a resultant lower risk of contamination and urinary leakage.

The transvesical Leadbetter-Politano method is based on anterior cystostomy. A submucosal tunnel is created, the ureter brought into the bladder posteriorly via a separate opening and sewn into the bladder from the inside. Afterwards, the bladder is closed by a watertight cystorrhaphy using a three-layer closure. The benefit of this method is a low risk of reflux, which may be accompanied, however, by ureteral obstruction.

Another viable technique of neoureterocystostomy is to create a nipple valve, where a nipple can be formed by turning the end of the ureter out on itself, placing the end of the nipple into the bladder, and fashioning the turned-back mucosal edge of the ureter to the recipient bladder mucosa with a running mucosal suture line. This technique involves a low rate of reflux but a higher incidence of obstruction than the aforementioned approaches [3, 7, 16].

About one-third of pediatric kidney transplant recipients have congenital anomalies of the kidney and the urinary tract (CAKUT) as the primary cause of renal failure. In addition, conditions such as neurogenic detrusor dysfunction secondary to meningomyelocele, bladder exstrophy or primary anuria with a subsequent minimal bladder volume may require reconstruction of the urinary tract even prior to transplantation. Depending on the individual anatomical situation prevailing, the donor ureter may be anastomosed with an augmented bladder or an ileal conduit.

Since opinions on the suitability of ureteral stents do diverge, their use is left to the surgeon's discretion. Some surgeons prefer a so-called single-J stent, which is placed in the renal pelvis and usually removed after 5–7 days posttransplant. In complex anatomical situations where the risk of ureteral obstruction is high, a double-J stent may be inserted, which extends from the renal pelvis to the bladder, and should usually be removed after 6–8 weeks posttransplant. Using a suprapubic urine catheter and a single-J stent may facilitate the distinction between urine output of the native kidney and that of the renal allograft [3, 7, 16].

Posttransplant Management

Early Postoperative Management (Table 1)

Initial assessment of the transplant recipient upon arrival from operating room includes assessment of hemodynamic and respiratory stability. Most

Table 1 Immediate postoperative assessment

Recipient information
Etiology of end-stage renal disease and any special considerations (ex. re: Risk of recurrent disease how does that change monitoring posttransplant ex. check daily protein/creatinine ratio for recurrent FSGS) Special urologic considerations such as vesicostomy, bladder augment, or mitrofanoff Pretransplant blood pressures and antihypertensive medication regimen Urine output pretransplant Preemptive transplant or dialysis pretransplant
Transplant information
Living donor or deceased donor Cold ischemia and warm ischemia time
Hemodynamic assessment
Blood pressure target parameters Low BP goal that would require fluid bolus High BP goal that would require prn antihypertensive Set target CVP

Lab monitoring plan

children are extubated immediately posttransplant with the occasional exception of the youngest recipients. Sign out from the anesthesia and OR team typically includes details on the intraoperative blood pressures and CVP, volume administered, metabolic correction, urine output, and any bleeding or need for intraoperative transfusion. The surgeon reports the cold and warm ischemia times and any surgical concerns. This is a good time for the care team to establish goals for the next 24 h such as target low and high blood pressure goals for which fluid boluses or prn antihypertensives should be administered. Target CVP goals are established at this time in addition to goals for urine output. Awareness of the patient's pretransplant blood pressure and antihypertensive regimens as well as native kidney urine output is important to help guide posttransplant management. Anticoagulation management plans are discussed with target levels depending on the patient's thrombosis risk. Review of the immunosuppression plan with details on the timing of induction and maintenance medication initiation are discussed. Renal Doppler ultrasound is performed in the immediate postoperative period to confirm graft vascular flow.

Hemodynamics

Attention should be focused on avoiding severe hypertension and hypotension in the immediate postoperative period. Invasive blood pressure monitoring via arterial line may be necessary in the first 48–72 hours. Blood pressure parameters, both high and low, should be established. In general, relatively higher blood pressures in the immediate postoperative period are tolerated to avoid renal ischemia. Knowledge of the patient's pretransplant blood pressure ranges is important to guide individualization of posttransplant goals.

Postoperative hypertension due to high volume administration and medications (steroids and calcineurin inhibitors) can be problematic, adding stress on the renal arterial anastomosis and increasing the risk of hypertensive seizure. However, caution should be used in the treatment of hypertension in the initial postoperative period. Blood pressures between 90th and 95th percentile for age, gender, and height may be tolerated depending on the clinical situation. The agents of choice for treatment of hypertension in the immediate postoperative period include short-acting vasodilators, beta blockers, or calcium channel blockers. In general, angiotensin converting enzyme (ACE) inhibitors and angiotensin II receptor antagonists are avoided in the early posttransplant period as they may induce renal insufficiency in the setting of diminished effective arterial blood volume. Diuretics may be helpful if hypervolemia is contributing to hypertension. Awareness of the patient's pretransplant antihypertensive regimen is helpful to guide posttransplant medication choices particularly if the regimen included medications such as beta blockers or clonidine that can be associated with a risk of rebound hypertension when stopped. If continuous infusion of antihypertensive medication is required, caution should be used with nicardipine as it may inhibit tacrolimus metabolism by cytochrome P450 resulting in overexposure and potential toxicity [17].

Hypotension and under perfusion of the adult-sized kidney in the pediatric patient is equally problematic. The treatment of choice for hypotension posttransplant is volume expansion with crystalloid and/or colloid. If possible, vasopressors are avoided, given the risk of renal vasoconstriction. An adult kidney in a small child needs a normal to high blood pressure and good intravascular volume for adequate perfusion. If the child has one or both native kidneys, one should be alert to hypotension and dehydration from polyuria.

Fluid and Electrolyte Management

Meticulous fluid and electrolyte management is critical for pediatric kidney transplant recipients. Additional intravascular volume repletion in the perioperative period is important to establish diuresis and avoid delayed graft function. Small children may require massive volume expansion to maintain adequate perfusion of the adult-sized kidney. It may be prudent to keep the small child intubated in the early postoperative phase if there are any signs of pulmonary edema. Central venous pressure monitoring is used to help assess intravascular volume status.

Intravenous fluid management posttransplant may include insensible fluids (300–400 ml/m^2/day) in addition to urine output replacement. Urine output is replaced with intravenous (IV) fluid, usually ½ normal saline with dextrose and water. In some cases, the postoperative diuresis is so large that hyperglycemia can result when 5% dextrose is used for urine replacement. Urine output is usually replaced mL/mL throughout the first 24 h with a gradual tapering of IV urine replacement as the patient's oral intake increases.

Supplemental loop diuretics or osmotic agents (mannitol) may be needed to facilitate diuresis in the oliguric patient. Although "renal dose dopamine" (3–5 mcg/kg/min) or other inotropic support to enhance renal vasculature dilatation was practiced by some centers, it is no longer considered beneficial. Providers should carefully administer medications associated with cytokine release (such as polyclonal and monoclonal T cell antibodies) in the patient who is volume expanded. Excessive volume administration may exacerbate hypertension. High volume diuresis may deplete electrolytes depending on the type of fluid replacement administered. At time of transplant, most patients have normal or elevated serum phosphorous levels. In the setting of delayed graft function, phosphate binders may be necessary to control hyperphosphatemia. With improved urine output, phosphaturia occurs due to hyperparathyroidism and/or the effect of calcineurin inhibitors. The goal phosphate level depends on the age of patient with higher acceptable levels in the young growing child. Oral phosphate supplements include preparations that contain potassium phosphate or a combination of sodium and potassium phosphate in either tablet or powder form. The choice of supplement depends on the patient's serum potassium and palatability. Hypomagnesemia may occur due to calcineurin inhibitor-induced renal magnesium wasting. A complication often seen with oral magnesium containing preparations is diarrhea. When this occurs, a dose reduction is necessary. In the patient who has delayed graft function, avoid magnesium-containing antacids to prevent the development of hypermagnesemia. Supplemental sodium bicarbonate may be needed in the postoperative period, especially in those with delayed graft function. Patients who are undergoing substantial diuresis and receiving high volume IV fluid may also need addition of bicarbonate containing solution to avoid metabolic acidosis.

Glucose management can be a problematic, especially in the pediatric patient with type I diabetes mellitus or in the patient on tacrolimus. An insulin drip may be required to maintain glycemic control. Once on a stable diet, patients can be switched to subcutaneous administration of long-acting insulin with a sliding scale of a short-acting preparation. Steroids complicate glycemic control and increased doses of insulin may be needed, especially when the patient is on higher doses of steroids in the first few months after transplant.

Urine Output

Close monitoring of urine output is very important in the immediate posttransplant period. In general, a Foley catheter is usually kept in the bladder for the first few postoperative days to avoid stressing the ureterocystostomy as well as to facilitate hourly assessment of urine output. It is important to ensure the Foley catheter in place and patent. Some centers also use suprapubic catheters. If the catheter is inadvertently discontinued or is not draining well, immediate evaluation is indicated. In most cases, the Foley will need to be replaced emergently to keep the bladder decompressed and to prevent tension on bladder-ureteral anastomosis.

Urine output in the early posttransplant period can range from oligo-anuria to polyuria and fluctuates depending on the clinical situation. Awareness of the patient's pretransplant urine output is useful in order to assess the adequacy of the urine output early posttransplant. The first step in addressing low urine output is to evaluate the patient's intravascular volume status (central venous pressure [CVP], blood pressure), in addition to ensuring patency of the Foley catheter. If the patient is hypovolemic, volume expansion with 10–20 mL/kg of isotonic saline can be administered. It is common for children to receive multiple fluid boluses in the first 24 h posttransplant. In contrast, if the patient is evaluated to be hypervolemic, a dose of intravenous furosemide can be given. If urine output does not improve with fluid resuscitation and diuretic challenge, a renal ultrasound with Doppler should be performed to confirm flow to the graft and assess for obstruction.

Reasons for a decrease in urinary output include volume depletion, urologic complications such as urine leak or obstruction, vascular thrombosis, calcineurin inhibitor nephrotoxicity and rejection. Urine leak or lymphocele is indicated by abdominal pain, distention, elevated creatinine and blood urea nitrogen (BUN), and fever. Ureteral stenosis or obstruction is indicated by decreased urine output/anuria, elevated BUN and creatinine, and pain over graft.

Gross hematuria may occur posttransplant due to the use of anticoagulation. However, there are some serious complications that merit consideration. The differential diagnosis of gross hematuria includes renal vein thrombosis, renal artery thrombosis, infection, ureteral stent related, recurrent disease, and thrombotic microangiopathy. Rapid evaluation with blood work, urine analysis, and microscopy, renal ultrasound with Doppler and possible biopsy is recommended.

Infection Surveillance and Prevention [18–20]

The use of perioperative intravenous antibiotics is transplant center specific. Many centers use a first-generation cephalosporin for the first 24–48 h in the nonallergic patient. Close daily attention to the patient's vital signs and physical examination is critical including evaluation of wounds, indwelling catheters, and drains. Lines, drains, and urinary catheters should be discontinued as soon as medically indicated to avoid risk of infection. Urine should be cultured and the sediment examined routinely as part of posttransplant management. Work-up for suspected infection in the pediatric kidney transplant recipient should include: physical examination, cultures (urine, blood, drains, and peritoneal fluid if indicated), chest X-ray, cytomegalovirus (CMV) and Epstein–Barr virus (EBV) polymerase chain reaction (PCR), and consider spinal tap if indicated.

Prophylaxis against *Pneumocystis jirovecii* using trimethoprim – sulfamethoxazole (TMP/SMZ) is indicated if the patient is not allergic. If the patient is TMP/SMZ allergic, dapsone or pentamidine can be used. Oral antifungal prophylaxis may be given for the first 1–3 months after transplant, usually in the form of nystatin, or clotrimazole lozenges, or fluconazole. Adjustment and close monitoring of the levels of calcineurin inhibitor is necessary when fluconazole is used due to the drug–drug interactions wherein the fluconazole inhibits the calcineurin inhibitor metabolism by cytochrome P450. Consensus recommendations guide the duration of therapy of viral prophylaxis for CMV with ganciclovir or valganciclovir based on the serostatus of the donor and recipient [19–20]. For CMV D+/R- patients, 3–6 months of prophylaxis with oral ganciclovir or valganciclovir is recommended. For CMV R+ patients, 3 months is recommended but 6 months should be considered if anti-lymphocyte induction is used. No prophylaxis is recommended in the CMV D−/R- patient. The dose for ganciclovir/valganciclovir needs to be adjusted according to the estimated creatinine clearance.

Anticoagulation

Screening for inherited and acquired thrombophilic risk factors is not routinely performed in all transplant recipients and is transplant center dependent. Indications for screening include family history of clotting and/or prior episodes of thrombosis. Preoperative screening typically includes assessment for protein C, S or antithrombin III deficiency, factor V Leiden, prothrombin gene mutations, and the presence of antiphospholipid antibodies. The use of prophylactic therapy with heparin, low-molecular-weight heparin, and/or aspirin to prevent thrombosis also varies by transplant center. Indications for the use of prophylaxis include identified thrombophilic risk factors, *en bloc*/young donor age, and difficult vascular reconstruction. In some centers, anticoagulation therapy is used prophylactically in all pediatric kidney transplant recipients. The duration of therapy generally varies from 3 months to 6 months depending on the indication.

A recent systematic review aimed to determine the effectiveness and safety of antithrombotic prophylaxis in pediatric and adult kidney transplant recipients evaluating 12 studies comprising 2370 patients were included in the evaluation [21]. The overall risk for developing renal graft thrombosis was lower in the group with antithrombotic prophylaxis compared to the control group (risk ratio 0.24, 95% confidence interval 0.12–0.49). Heparin was the preferred drug, followed by acetylsalicylic acid or a combination of acetylsalicylic acid, heparin, and dipyridamole. Adverse effects were reported rarely, with minor bleeding as the main complication.

Posttransplant Complications

Acute Kidney Injury

Several factors can contribute to posttransplant acute kidney injury. These include donor type and age, technique of organ preservation, adequacy of volume replacement during and after surgery, and cold and warm ischemia times. Tubular damage may be aggravated by the use of cyclosporine or tacrolimus. Recovery of renal function can be divided into three broad categories: rapid recover of graft function, slow, or delayed. Table 2 summarizes causes of graft dysfunction. Delayed graft function has a specific definition and refers to the need for dialysis in the first week posttransplant. This occurs in less than 10% of pediatric kidney transplant recipients [22]. Indications for dialysis posttransplant include electrolyte abnormalities and/or significant fluid overload leading to pulmonary compromise and hypertension. Caution should be used when initiating dialysis in the early posttransplant period to avoid significant intravascular volume depletion that can compromise renal perfusion.

Surgical Complications

Graft Thrombosis

Graft thrombosis may be either arterial or venous and usually develops within the first 3 days posttransplant, its incidence ranging between 0.5% and 8%. Because thrombosis is facilitated by a previous thrombotic tendency, thrombophilia screening of transplant recipients prior to surgery is as essential as is antithrombotic management, which will be discussed below. Early thrombosis may be due to surgical techniques. Clinical symptoms are, among others, cessation of urine output, swelling of the transplant kidney, tenderness, graft function deterioration, and hematuria. Diagnosis is possible by means of Doppler ultrasound. Unfortunately, confirmed thrombosis usually requires graft

Table 2 Causes of graft dysfunction[a]

Causes of graft dysfunction	How to assess	Suggested management
Volume depletion	Fluid balance/weight CVP and hemodynamic assessment	Fluid bolus
Acute tubular necrosis	Urine analysis	Close monitoring of fluid balance and hemodynamics
Vascular complications: Renal artery stenosis Renal vein thrombosis	Urgent transplant ultrasound with Doppler interrogation	Immediate surgical evaluation/ intervention
Urologic: Urinary obstruction Urinary leak	Imaging: Transplant ultrasound to look for collecting system dilation Nuclear medicine study to assess for urinary leak Body fluid creatinine assessment	Immediate surgical evaluation/ intervention
Calcineurin nephrotoxicity	Drug levels Kidney transplant biopsy	Pharmacokinetic studies Assess if any drug interaction Consider adjustment of maintenance therapy
Hyperacute rejection	Donor-specific antibodies Kidney transplant biopsy	Treatment of rejection

[a] Recurrence of primary disease and thrombotic microangiopathy are discussed in separate chapters

nephrectomy, although rare cases of successful graft salvage by thrombectomy and fibrinolysis are reported in the literature [3, 17, 18].

Renal Artery Stenosis

Renal artery stenosis is the most common vascular complication experienced after kidney transplantation. It occurs late, usually between 3 months and 2 years posttransplant, its incidence ranging from 2% to 10%. Refractory arterial hypertension and graft dysfunction are typical clinical signs of renal artery stenosis, which usually develops in the area of the anastomosis. Its causes may be technical error, kinking of the vessel and sometimes artherosclerotic plaques in older recipients, just like hyperplastic response of endothelial or smooth muscle to occult intraoperative trauma and proliferative responses to immunological stimuli. It can be diagnosed by means of Doppler ultrasound, CT, NMR angiogram, or arteriogram. Treatment consists in percutaneous transluminal angioplasty with balloon dilatation or placing of stents. Sometimes surgical correction is necessary as well [3, 7, 23, 24].

Hemorrhage

Postoperative bleeding is a rare complication following kidney transplantation. Early hemorrhage may arise from latent small vessels in the renal hilum, which did not become apparent at the time of reperfusion, due to vasospasm. Hence, meticulous preparation of the allograft and hemostasis are of major importance. Late hemorrhage may occur as a result of mycotic aneurysm ruptures or perianastomotic infection. Clinical signs of hemorrhage may be intense graft site or back pain, accompanied by a drop in hematocrit, and hemoglobin, and by symptoms of vascular collapse. In such events, immediate surgical intervention is required to prevent life-threatening bleeding [3, 7].

Lymphocele

Lymphoceles are lymph collections between the inferior kidney pole and the bladder, which develop due to insufficient ligation of afferent lymphatics overlying the iliac vessels. Their incidence ranges between 0.6% and 18%. Most lymphoceles are small and asymptomatic.

However, some of them may lead to clinical symptoms such as leg swelling indicative of deep vein thrombosis, abdominal mass, ureteral obstruction, and graft dysfunction due to hydronephrosis. Occasionally, lymphoceles may cause incontinence secondary to bladder compression, scrotal mass, or cutaneous lymph fistulae. Lymphoceles are identifiable by means of ultrasound as roundish, sonolucent, septated mass. Needle aspiration of the fluid does confirm diagnosis if the fluid is clear and has a high protein content, whereas the creatinine concentration is equal to that of serum. Treatment modalities of symptomatic lymphoceles encompass aspiration, sclerotherapy, drain placement, laparoscopic surgery, and open surgery. In the case of surgical intervention, marsupialization of the lymphocele and internal drainage in the peritoneal cavity is the method preferably employed [3, 5].

Urologic Complications

Urinary Leakage

Urinary leaks may develop within the first few days posttransplant or, in case of delayed graft function, at the onset of diuresis. They can occur at the level of the bladder, the ureter, or the renal pelvis, and may be caused by faulty handling of the donor ureter, ureteral slough secondary to disruption of ureteral blood supply, infection, hematoma, or rupture secondary to a tight ureteral stenosis. Clinical signs are, for example, decreased urine volume, severe pain, graft dysfunction, fever, wound drainage, and sepsis. A fluid collection can be diagnosed by ultrasound, should be drained under sterile conditions, and is typically accompanied by a high concentration of creatinine. In the event of urinary leakage, remedial action should be taken without delay. Placement of a urethral catheter can relieve the intravesical pressure and occasionally reduce or even stop the leakage altogether. Sometimes nephrostomy may be a suitable tool to diagnose the leak and to control the urine flow. Cases of ureteral leakage call for early surgical exploration, and usually necessitate reimplantation of the ureter into the bladder in an anti-refluxing fashion and placement of an indwelling double-J stent. If the ureter proves too short, the native ureter may be used to perform a ureteropyelostomy [3, 5, 23].

Urinary Tract Obstruction

Urinary tract obstruction is most often due to clots in the urinary tract, postoperative edema, or surgical complication. Ureteral obstruction is the most common urinary complication observed after kidney transplantation, which may happen early or late in the postoperative course. It is often due to technical problems or fibrosis and also may be due to BK polyomavirus infection or rejection episodes. Ureteral obstruction predominantly manifests itself as graft function deterioration without pain. Hydronephrosis can be shown by ultrasound, and hemodynamically relevant hydronephrosis by renal scintigraphy with furosemide. Depending on the site where the ureteral obstruction resides, a neoureterocystostomy, ureteropyelostomy, or nephrostoma may be necessary to perform [3, 5, 23].

Peritoneal Fluid Accumulation

After transplant, patients who were on peritoneal dialysis prior to transplant may have significant peritoneal fluid accumulation, likely due to peritoneal irritation from long-standing exposure to dextrose containing dialysate. Intermittent drainage of the abdomen via the peritoneal catheter may be warranted in the setting of patient discomfort or if there is concern for increased intra-abdominal pressure.

Abstract

During its lifetime, the renal allograft is at continuous risk for the development of rejection due to HLA and non-HLA incompatibility with the recipient which is why lifelong immunosuppressive therapy is required. The goal of immunosuppressive therapy posttransplantation in pediatric renal transplant recipients is to prevent acute and chronic rejection and support adherence while minimizing drug side effects and infectious complications. Most therapies alter immune response mechanisms but are not immunologically specific, and a careful balance is required to find the dose that prevents rejection of the graft, while minimizing the risks of over-immunosuppression leading to increased morbidity and mortality from infection and cancer. Although data from adult renal transplantation trials are used to help guide management decisions in pediatric patients, immunosuppressive therapy in pediatric renal transplant recipients is often modified due to the unique dosage requirements and clinical effects of these agents on the growth and development of children, who are less likely to have had prior exposure to pathogens. The optimal immunosuppressive therapy posttransplant has to be individualized to patient characteristics, and ideally should be titrated to the specific immune-risk thresholds of the recipient and to minimize any negative impact on growth. Evaluation of risk factors involves a comprehensive evaluation of clinical, biopsy, HLA mismatch, and viral findings, and the potential for recurrence of certain primary renal diseases such as lupus nephritis or focal segmental glomerular sclerosis. Allograft survival rates vary among the various immunosuppressive agents due to patient-specific clinical characteristics, such as age, obesity, ethnicity, hyperlipidemia, arterial hypertension, proteinuria and/or delayed allograft function. The "one size fits all" strategy needs to evolve into tailored strategies based upon a child's medical history and circumstances.

Introduction

The common immunosuppressive agents used in pediatric renal transplantation include antibodies to cell surface antigens on lymphocytes (anti-thymocyte globulin (ATG)), anti-interleukin 2 (IL-2) receptor antibodies, glucocorticoids, the calcineurin inhibitors tacrolimus and ciclosporin, the lymphocyte proliferation inhibitors mycophenolate mofetil (MMF) and azathioprine, and the mammalian target of rapamycin (mTOR) inhibitors sirolimus and everolimus. The optimal prophylactic induction immunosuppressive therapy remains controversial. Maintenance regimens consist of a combination of immunosuppressive agents that differ in their mechanism of action. This strategy minimizes morbidity and mortality associated with each class of agent while maximizing overall effectiveness. An adequate maintenance level of immunosuppression is required to dampen the immune response to the allograft. The level of chronic immunosuppression is slowly decreased over time to help lower the overall risk of infection and malignancy; these risks directly correlate with the degree of overall immunosuppression.

Allograft survival rates vary among the various immunosuppressive agents due to patient-specific clinical characteristics, such as age, obesity, ethnicity, hyperlipidemia arterial hypertension, proteinuria, delayed allograft function, and some donor-related factors such as living-related versus deceased kidney donation. Immunosuppressive agents should therefore be chosen in part based on patient characteristics. Other issues to be considered are related to the immunologic history of the patient, such as ABO compatibility and the degree of HLA mismatching, presensitization, retransplantation, history of acute rejection episodes, and the risk of recurrent disease.

Current immunosuppressive agents reduce acute rejection, but do not induce reliable or durable tolerance that can be accurately measured. A few patients with organ transplants successfully can withdraw their immunosuppression without rejecting their grafts for long periods of time, but the hunt for biomarkers to harness this “operational” tolerance state have remained elusive [1]. However, these are rare exceptions, and such patients may eventually reject, even after years as this operational state of tolerance is unstable and poorly understood. Much additional work is needed to define optimal immunosuppressive regimens in pediatric renal transplant recipients, particularly with respect to newer and evolving regimens, specifically their evaluation of safety in the immunologically naive pediatric population.

This chapter focuses on immunosuppressive therapy in pediatric renal transplant recipients and the diagnosis and management of allograft rejection.

Classification of Immunosuppressive Agents

Immunosuppressive and immunomodulatory drugs can be pharmacologically categorized on the basis of their mechanism of action. The three-signal model of T cell activation and proliferation is helpful in understanding the molecular mechanisms and site of action of various immunosuppressive drugs. Figure 1 depicts a schematic representation of the three-signal model along with the site of action of common immunosuppressive drugs. Signal 1 features antigen-presenting cells (APCs; macrophages and dendritic cells) presenting the foreign antigen to the T lymphocyte, activating the T cell receptor (TCR), which further relays the signal through the transduction apparatus known as the CD3 complex. Signal 2 is a nonantigen-specific co-stimulatory signal which occurs as a result of binding of the B7 molecule on the APC to CD28 on the T cell. Both signal 1 and signal 2 activate signal transduction pathways: the calcium–calcineurin pathway, mitogen-activated protein (MAP) pathway, and the nuclear factor-κB (NF-κB) pathway. This in turn leads to increased expression of interleukin-2 (IL-2), which through its receptor (IL-2R) activates the cell cycle (signal 3). Signal 3 activation requires the enzyme target of rapamycin for translation of mRNA and cell proliferation. Thus, various drugs act on different cellular signals and achieve immunosuppression by a number of mechanisms: depleting lymphocytes, diverting lymphocyte traffic, or blocking lymphocyte response pathways.

Induction Immunosuppressive Therapy

Induction refers to the administration of an intensive immunosuppressive regimen during the perioperative period. The rationale behind this approach is that the risk of acute rejection is greatest in the first weeks or months posttransplant. Induction therapies often involve the use of polyclonal or monoclonal antibodies to achieve rapid and profound early immunosuppression. *Polyclonal antibodies* used for this purpose include those against thymocytes (anti-thymocyte globulin (ATG)); *monoclonal antibodies* include basiliximab (a chimeric human–murine anti-CD25 or anti–interleukin-2 receptor antibody), and alemtuzumab (an anti-CD52 antibody targeting both B and T cells), which is not always readily available.

Each protocol may have specific advantages and/or disadvantages in a particular patient population [3]. The optimal prophylactic induction

Fig. 1 Individual Immunosuppressive Drugs and Sites of Action in the Three-Signal Model. Anti-CD154 antibody has been withdrawn from clinical trials but remains of interest. FTY720 engagement of sphingosine-1-phosphate (S-1-P) receptors triggers and internalizes the receptors and alters lymphocyte recirculation, causing lymphopenia. Antagonists of chemokine receptors (not shown) are also being developed in preclinical models. MPA denotes mycophenolic acid. (Modified according to [2])

immunosuppressive therapy to prevent renal transplant rejection remains therefore controversial. Figure 2 presents the induction antibody use from 2007–2018, as reported in the Scientific Registry of Renal Transplant Recipients (SRTR) 2018 annual report, where use of ATG has increased and that of anti-IL2R and no induction has decreased over time. In Europe, as reported by the Cooperative European Paediatric Renal Transplant Initiative (CERTAIN) Registry, 60% of pediatric renal transplant recipients do not receive any induction therapy, 35% receive basiliximab, and 5% ATG [4]. Hence, the frequency of use of the different immunosuppressive antilymphocyte regimens for induction therapy varies markedly between North America and Europe.

Induction therapy produces the greatest benefits in groups at high risk for allograft rejection. These high-risk groups include African Americans, recipients of kidneys with prolonged cold ischemia time, and those at high immunologic risk, particularly individuals who are pre-sensitized. The sequential induction regimen of thymoglobulin followed by a combination of tacrolimus and MMF with or without steroids is recommended in these high-risk groups.

The Polyclonal Lymphocyte-Depleting Antibody Thymoglobulin

Because of the redundancy of the immune system, polyclonal antibodies, which have a broad specificity, should theoretically be more effective in induction therapy than monoclonal antilymphocyte agents. *Thymoglobulin* is a rabbit-derived polyclonal antibody preparation approved for the treatment of rejection and recently also for induction therapy by the Federal Drug Administration (FDA) in USA. Thymoglobulin contains antibodies to a wide variety of T cell antigens and HLA antigens. Polyclonal antibodies act in three ways: By

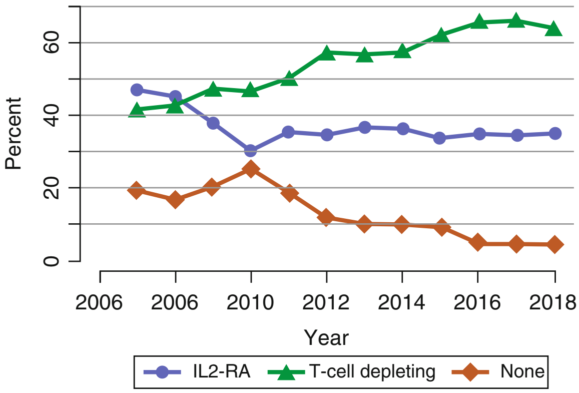

Fig. 2 Induction agent use in pediatric kidney transplant recipients in the United States of America. Immunosuppression at transplant reported to the Organ Procurement and Transplantation Network (OPTN) (https://pubmed.ncbi.nlm.nih.gov/31898417). IL2-RA, interleukin-2 receptor antagonist

activating or altering the function of lymphocytes, by lysing lymphoid cells, and by altering the traffic of lymphoid cells and sequestering them. These antibodies are potently immunosuppressive, but often produce side effects. By triggering T cells, they generate significant first-dose effects, with the release of tumor necrosis factor alpha (TNFα), interferon γ (IFN-γ), and other cytokines, causing a first-dose reaction (flu-like syndrome, fever, and chills).

Thymoglobulin induction is usually dosed from 1 to 6 mg/kg per dose, and the duration may range from 1 to 10 days, although a more typical regimen is 1.5 mg/kg per dose for 3–5 days [5–9]. The optimal total induction dose is felt to be 6 mg/kg [7, 10]. Higher doses and prolonged duration of induction agents are thought to be associated with an increased risk of infection and the potential development of lymphoma, whereas cumulative doses of less than 3 mg/kg may not effectively prevent acute rejection [10].

The Monoclonal IL-2 Receptor Antibody Basiliximab

Full T cell activation leads to the calcineurin-mediated stimulation of the transcription, translation, and secretion of IL-2, a key autocrine growth factor that induces T cell proliferation. It also leads to the de novo expression of CD25 on the T cell surface. Thus, an attractive therapeutic option is abrogation of IL-2 activity via the administration of anti-IL-2 receptor antibodies resulting in attenuated signaling via the high-affinity IL-2 receptor. The only anti-IL-2 receptor antibody currently available is basiliximab, a chimeric monoclonal antibody that has been approved by the FDA for use in renal transplantation in adults and pediatric patients. Basiliximab is directed against CD25, the IL-2 receptor 55 kDa α-chain. However, IL-2 receptor functions are partially redundant, because other cytokine receptors have overlapping functions, e.g., IL-15 receptors. Therefore, saturating IL-2 receptors produces stable, but relatively mild immunosuppression and is only effective in combination with other immunosuppressants. In contrast to thymoglobulin, basiliximab is not a lymphocyte-depleting antibody.

The dosing schedule for basiliximab is the following: Intravenous administration of two 10 mg doses to children <35 kg in weight and two 20 mg doses to children ≥35 kg in weight, with the first dose given peri-transplantation and the second on day four posttransplant. In patients on concomitant immunosuppression with ciclosporin and azathioprine, the mean duration of IL-2 receptor saturation is 42 ± 16 days [11], in patients on ciclosporin with MMF, MMF reduces basiliximab clearance and prolongs CD25 saturation from 5 to 10 weeks [12].

Two large prospective randomized controlled trials in pediatric renal transplant recipients showed that induction therapy with basiliximab in patients with low to standard immunological risk on maintenance therapy (tacrolimus in conjunction with azathioprine, or ciclosporin in conjunction with MMF) did not lead to a statistically significant reduction in the incidence of acute rejection episodes [13, 14]. In contrast, the

KDIGO clinical practice guidelines recommend induction therapy for all adult patients, with an IL-2 receptor blocker as first line for those not at high immunological risk [15]. There is some evidence favoring the use of IL-2 receptor blockers over no induction in adult renal transplantation [16]. However, it has been pointed out in the more recent literature that these studies mainly used outdated maintenance regimens [17]. No large randomized trial has examined the effect of IL-2 receptor antibodies or rabbit ATG induction versus no induction in patients receiving tacrolimus, mycophenolic acid, and corticosteroids. With this triple maintenance therapy, the addition of induction may achieve an absolute risk reduction for acute rejection of only 1–4% in standard-risk patients without improving renal allograft or patient survival. In contrast, rabbit ATG induction lowers the relative risk of acute rejection by almost 50% versus IL-2 receptor antibodies in patients with high immunological risk. These recent data raise questions about the need for IL-2 receptor antibodies in renal transplantation, as it may no longer be beneficial in standard-risk transplantation although augmentation of immunosuppression may allow corticosteroid minimization and may be inferior to rabbit ATG in high-risk situations. Updated evidence-based guidelines are necessary to support clinicians deciding whether and what induction therapy is required for their transplant patients today [17].

Alemtuzumab (Campath-1H, MabCampath) is a humanized IgG1 monoclonal antibody directed against CD52, a glycoprotein expressed on mononuclear cells, including T and B lymphocytes, monocytes, and natural killer cells [18]. Its efficacy for induction and maintenance with low-dose calcineurin inhibitors was first introduced by Calne et al. [19] and later supported by the Pittsburgh group [20] in adults and children. Alemtuzumab induction has been associated with lower rates of acute rejection than basiliximab and daclizumab in low immunological risk patients and was associated with similar efficacy as compared with rabbit anti-thymocyte globulin in high-risk patients [21], although most of these studies have involved adult renal transplant recipients. There is also pediatric experience that supports this efficacy claim, especially in highly sensitized, high-risk children [22, 23]. A significant reduction of white blood cell and absolute lymphocyte counts have been observed in children receiving alemtuzumab treatment up to 1 year posttransplant [24].

As a result, there is presently no consensus among pediatric renal transplantation centers regarding the use and regimen for immunosuppressive induction therapy, although there have been moves for standardization of immunosuppressive regimens for pediatric renal transplant recipients in some countries (e.g., United Kingdom). Considerations in choosing the appropriate agent include the efficacy in the patient population (e.g., recipients with high or low immunological risk of graft loss), the side effect profile, and the concomitant immunosuppressive therapy (corticosteroid avoidance, early corticosteroid withdrawal, or conventional corticosteroid therapy).

Maintenance Immunosuppressive Therapy

Maintenance immunosuppressive therapy is administered to renal transplant recipients to help prevent acute rejection. Although an adequate level of immunosuppression is required to dampen the immune response to the allograft, the level of chronic immunosuppression is slowly decreased over time to help lower the overall risk of infection and malignancy; these risks directly correlate with the degree of overall immunosuppression. The type of immunosuppression may also be varied to decrease the risk of developing chronic antibody-mediated rejection, the most common underlying long-term cause of renal allograft loss. Conventional maintenance regimens consist of a combination of immunosuppressive agents that differ in their mechanism of action. This strategy minimizes morbidity and mortality associated with each class of agent while maximizing overall effectiveness. Such regimens may vary by transplant center and geographic area.

There are a number of important issues to consider when deciding upon the immunosuppressive protocol to administer in a particular patient: The risk for acute rejection and allograft loss is highest in the first 3 months after transplantation. As a result, immunosuppression should be at its highest level during this period. The occurrence of the most serious side effects of immunosuppressive therapy, infections and malignancy, correlate with the total amount of immunosuppression. It is therefore essential that immunosuppression is gradually tapered to a maintenance level by 6–12 months posttransplant although reduction of immunosuppression may result in acute rejection and increased total burden of chronic immunosuppression as part of treatment.

Renal allograft survival rates vary among the various immunosuppressive agents due to patient-specific clinical characteristics, such as age, obesity, ethnicity, hyperlipidemia, arterial hypertension, proteinuria, and/or delayed allograft function. Immunosuppressive agents should therefore be chosen in part based on patient characteristics. Other issues to be considered are related to the “immunologic” history of the patient including degree of HLA mismatching, history of sensitization as determined by panel reactive antibodies, primary transplant or a re-transplant, history and number of acute rejection episodes in the current transplant, and the risk of recurrence of underlying kidney diseases such as focal segmental glomerulosclerosis (FSGS) and atypical hemolytic uremic syndrome (HUS).

The optimal maintenance immunosuppressive therapy in pediatric renal transplantation is not established. The major immunosuppressive agents currently used in various combination regimens are tacrolimus, ciclosporin, MMF, azathioprine, everolimus, sirolimus, and glucocorticoids (primarily oral prednisone or methylprednisolone). Most transplant centers currently utilize a maintenance regimen consisting of triple immunosuppression therapy with a calcineurin inhibitor (tacrolimus or ciclosporin), an anti-metabolite (MMF or azathioprine), and in some patients prednisone or methylprednisolone. Everolimus or sirolimus is also used by some transplant centers in triple therapy regimens, sometimes in place of the calcineurin inhibitor or the antimetabolite. Within the NAPRTCS registry, marked changes in the type of maintenance immunosuppression and dosing strategies have been observed over time [1]. These are substantially caused by the introduction of drugs such as MMF and tacrolimus (Table 1). In the European CERTAIN Registry in the transplant era 2010–2018, the most popular immunosuppressive regimen at posttransplant day 30, applied in 56% of patients, was triple therapy with tacrolimus, MMF, and prednisone [2]. According to the North American Scientific Registry of Transplant Recipients (SRTR) 2018 annual report,

Table 1 Observed drug utilization rates in North American pediatric renal transplant recipients among transplanted grafts with $\geq$30 days function that have occurred since 1996. (Data are from Ref. [25])

the most used maintenance immunosuppression in the USA is a combination of tacrolimus with MMF with or without steroids.

The Calcineurin Inhibitors Ciclosporin and Tacrolimus

Ciclosporin, a lipophilic cyclic peptide of 11 amino acid residues, and tacrolimus, a macrolide antibiotic, are drugs with similar mechanisms of action that have become major maintenance immunosuppressive agents used in transplantation. Ciclosporin and tacrolimus act by inhibiting the calcium-dependent serine phosphatase calcineurin, which normally is rate limiting in T cell activation.

Ciclosporin and tacrolimus are both variably absorbed and are metabolized extensively by the liver (via the cytochrome P450 system). Neither ciclosporin nor tacrolimus is affected by alterations in renal function. Both ciclosporin and tacrolimus bind to cells and to plasma components (primarily lipoproteins for ciclosporin and albumin for tacrolimus) in the blood; consequently, they must be assayed in whole blood. Many drugs and agents can affect ciclosporin and tacrolimus levels through effects on their absorption or metabolism (Table 2).

Table 2 Examples of common drug interactions of immunosuppressants used in solid-organ transplantation: Cyclosporine, tacrolimus, sirolimus, and everolimus

Common types of drug interactions	Examples of interacting drugs
Coadministration of drugs that inhibit CYP3A metabolism and/or P-gp efflux can increase immunosuppressant whole blood concentrations, leading to significant toxicities	Amiodarone ART-boosting agents (eg, ritonavir, cobicistat) Azole antifungals (eg, fluconazole, posaconazole, voriconazole) HIV protease inhibitors (eg, atazanavir, nelfinavir, saquinavir) Macrolide antibiotics (except azithromycin) Non-dihydropyridine calcium channel blockers Ombitasvir-paritaprevir-ritonavir with or without dasabuvir (an HCV, direct-acting antiviral regimen) Grapefruit juice
Coadministration of drugs that induce CYP3A metabolism and/or P-gp efflux pumping can decrease immunosuppressant whole blood concentrations, increasing the risk of organ rejection	Antiseizure drugs, enzyme inducing (eg, carbamazepine, fosphenytoin, oxcarbazepine, phenobarbital, phenytoin, primidone) Enzalutamide Nafcillin Rifamycins (eg, rifabutin, rifampin, rifapentine) St. John's wort
Coadministration of nephrotoxic drugs with cyclosporine or tacrolimus can cause additive or synergistic kidney injury	Aminoglycosides Amphotericin B Colchicine Nonsteroidal antiinflammatory drugs (NSAIDs)
Coadministration of drugs that increase serum potassium with cyclosporine or tacrolimus may cause severe hyperkalemia	ACE inhibitors/ARBs Amiloride Spironolactone Triamterene Trimethoprim, trimethoprim-sulfamethoxazole (cotrimoxazole)
Coadministration of statin drugs with cyclosporine can increase statin levels and risk of myotoxicity	Atorvastatin Lovastatin Pitavastatin Rosuvastatin Simvastatin

CYP, cytochrome P450 metabolism; P-gp, P-glycoprotein drug efflux pump; ART, HIV antiretroviral therapy; HIV, human immunodeficiency virus; HCV, hepatitis C virus; ACE, angiotensin-converting enzyme; ARB, angiotensin II receptor blocker

Since the absorption of ciclosporin is decreased and its metabolism increased in children compared to adults, relatively higher dosages are required in pediatric patients. Ciclosporin is usually administered initially as 8–15 mg/kg per day in divided doses (or intravenously using one-third the oral dose over a 24-h period) during the induction phase, with target trough blood levels of 150–300 μg/L for the first 3–6 months posttransplant. Doses are reduced after 3–6 months (typically 4–6 mg/kg daily); long-term target trough blood levels of 75–125 μg/L appear to provide comparable patient and graft survival as higher blood levels but with less risk of malignancy [26]. Generic forms of ciclosporin are available, but they may not be equivalent and readily interchangeable, and knowledge of the characteristics of the oral formulations is necessary before switching between them.

Tacrolimus is 20- to 30-fold more potent than ciclosporin and, therefore, is administered at a 20-fold lower dose. Initial dosing is usually 0.2–0.3 mg/kg per day in two divided doses orally (or 0.05–0.1 mg/kg per day intravenously over 24 h), and target trough levels are 5–15 μg/L. Since tacrolimus is more water soluble than ciclosporin, it is not as dependent upon bile salts for absorption. However, food intake can reduce the absorption of tacrolimus by up to 40%; thus, it is recommended that this agent be taken on an empty stomach [27] or at least patient takes medication the same time every day. In addition, tacrolimus is best absorbed in the morning. There is also an extended-release formulation of tacrolimus available that is designed to be given once per day with similar efficacy and safety.

Genetic polymorphisms in genes encoding tacrolimus-metabolizing enzymes partly explain the interpatient variability in tacrolimus pharmacokinetics [28]. The key enzymes involved in the metabolism of tacrolimus are CYP3A4 and CYP3A5 [29]. Individuals are considered expressers of CYP3A5 if they carry at least one CYP3A5*1 allele, whereas individuals homozygous for the CYP3A5*3 allele are classified as CYP3A5 nonexpressers. In addition to CYP3A5*3, the CYP3A5*6 and CYP3A5*7 variant alleles can also lead to nonfunctional CYP3A5 protein [30]. There are also ethnic distribution differences of CYP3A5 variant alleles with expressers (carriers of the CYP3A5*1 variant allele) being more frequently found among non-Caucasian populations. Approximately 10–40% of Caucasians are CYP3A5 expressers, 33% of Asians and 55% of African Americans [31]. CYP3A5 expressers require a tacrolimus dose that is approximately 1.5-fold to twofold higher than nonexpressers to reach the same exposure [32, 33]. This implies that following a standard, body weight–based tacrolimus dose, CYP3A5 expressers are prone to have subtherapeutic tacrolimus concentrations whereas nonexpressers are expected to have supratherapeutic tacrolimus concentrations [34].

The overall conclusion from data in adult renal transplant recipients is that tacrolimus-based immunosuppression is associated with decreased acute rejection rates, a superior long-term renal allograft function and more favorable cardiovascular risk profile than ciclosporin microemulsion–based immunosuppression which translates into improved long-term renal allograft survival. In pediatric patients, the efficacy and safety of tacrolimus and ciclosporin were compared in one multicenter trial in 196 patients, who were randomly assigned to receive either tacrolimus or ciclosporin microemulsion administered concomitantly with azathioprine and corticosteroids [35]. Tacrolimus therapy resulted in a significantly lower incidence of acute rejection (36.9%) compared with ciclosporin therapy (59.1%) ($p = 0.003$). The incidence of steroid-resistant rejection was also significantly lower in the tacrolimus group compared with the ciclosporin group (7.8% versus 25.8%, $p = 0.001$). The difference was also significant for biopsy-confirmed acute rejection (16.5% versus 39.8%, $p < 0.001$). Patient survival at 1 year was similar (96.1% versus 96.6%); ten grafts were lost in the tacrolimus group compared with 17 graft losses in the ciclosporin group ($p = 0.06$). The tacrolimus group had a significantly better estimated GFR at 1 year. A follow-up study at 4 years showed that patient survival was similar (94% versus 92%, $p = 0.86$), but renal allograft survival (86% versus 69%; $p = 0.025$) and mean estimated glomerular filtration rate significantly favored tacrolimus [36]. Cholesterol remained significantly higher with ciclosporin throughout follow-up. Three patients in each arm developed posttransplant lymphoproliferative disorder (PTLD). Incidence of new onset of diabetes mellitus after transplantation was not different. Therefore, tacrolimus is significantly more effective than ciclosporin in preventing acute rejection in pediatric renal recipients, and renal function and graft survival are also superior with tacrolimus.

Ciclosporin and tacrolimus have similarities and differences in their *toxicity profiles* (Table 3). Both can cause nephrotoxicity, hyperkalemia, hyperuricemia with occasional gout, hypomagnesemia secondary to urinary loss, arterial hypertension, diabetes mellitus, and neurotoxicity, especially tremor. In the European pediatric study, the incidence of hypomagnesaemia was significantly higher in the tacrolimus-treated group (34%) compared with the ciclosporin-treated group (12.9%) [35]. Similarly, diarrhea was more frequent in tacrolimus-treated patients (13.6% versus 3.2%). Hypertrichosis, gingival hyperplasia, and flu-like syndrome were reported only in ciclosporin-treated patients and tremor was reported only in tacrolimus-treated patients [35]. Those results are similar to adults where tremor is consistently more common with tacrolimus and hirsutism and gum disease more common in ciclosporin-treated patients [37]. Arterial hypertension and hyperlipidemia are more commonly observed with ciclosporin. In the European pediatric study, the mean total cholesterol levels were reported to decrease in the tacrolimus group and increase in the ciclosporin group at the end of 6 months [24]. In the multicenter analysis from the European CERTAIN Registry, the prevalence of dyslipidemia was 95% before transplantation and 88% at 1-year posttransplant [38]; the use of tacrolimus and of MMF was associated with significantly lower concentrations of all lipid parameters compared to regimens containing ciclosporin and mTOR inhibitors. Regimens consisting of ciclosporin, MPA, and corticosteroids as well as of ciclosporin, mTOR inhibitors, and corticosteroids

Table 3 Semi-quantitative comparison of safety profiles of current primary immunosuppressive compounds

[c] Wound healing problems including lymphocele formation

were associated with a threefold and 25-fold increased risk of having more than one pathologic lipid parameter as compared to the use of tacrolimus, MMF, and corticosteroids [38]. Similarly, in adults, several studies have shown that lipid levels are much lower in tacrolimus-treated patients than in those receiving ciclosporin [37]. The improved lipid profiles on tacrolimus may contribute to a better long-term outcome with less cardiovascular morbidity.

On the other hand, tremor and glucose intolerance are more common with tacrolimus. In the pediatric multicenter European study there was, however, no difference in the incidence of new-onset insulin-dependent diabetes mellitus between tacrolimus- (3%) and ciclosporin-treated patients (2.2%) [35, 36]. The incidence of diabetes mellitus with tacrolimus immunosuppression has become less frequent in recent randomized trials comparing these two calcineurin inhibitors [39]. Posttransplant diabetes mellitus can regress after dose reduction in some but not all patients. Both reduction of corticosteroid dosage and a low target trough tacrolimus concentration contribute to the recent marked reduction of the incidence of diabetes mellitus under tacrolimus immunosuppression in both adults and children [35, 37]. Ciclosporin may also be associated with coarsening of facial features, especially in children. Bone pain that is responsive to calcium channel inhibitors may also occur with ciclosporin or tacrolimus use [40].

The most common serious problem with the calcineurin inhibitors is *nephrotoxicity*, with both a reversible vasomotor component and an irreversible component. Both ciclosporin and tacrolimus can cause acute elevations in serum creatinine that reverse with reduction of the dose, apparently caused by renal vasoconstriction which itself may be mediated by calcineurin inhibition. Chronically, ciclosporin and tacrolimus can induce tubular atrophy and interstitial fibrosis with characteristic hyalinosis of the afferent arteriole [41]. The importance of this lesion is apparent from studies in cardiac and liver transplant recipients, in whom ciclosporin or tacrolimus use is associated with chronic kidney disease progressing to end-stage kidney disease in a significant fraction of patients [42]. This problem was more acute at a time, when higher doses of ciclosporin were administered for longer periods. Currently, ciclosporin and tacrolimus toxicity are associated with only mild to moderate declines in renal function. However, as the number of patients with long-standing non--renal transplants increases, there is increasing concern about future end-stage kidney disease in this population. It is important to establish the diagnosis of calcineurin inhibitor nephrotoxicity by percutaneous renal biopsy and reduce or stop calcineurin inhibition whenever possible [39, 43, 44].

There is no difference in the incidence of PTLD between tacrolimus- and ciclosporin-microemulsion-treated recipients when used in combination with azathioprine and corticosteroids [1% (1/103) versus 2.1% (2/93)] [35] or when used in conjunction with MMF/corticosteroids (1.4% versus 2%) [45]. This is similar to adults, in whom recent large, randomized studies could not show any difference in the incidence of malignancy between patients treated with tacrolimus or ciclosporin [37].

Therapeutic Drug Monitoring

Tacrolimus and ciclosporin are drugs with a *narrow therapeutic index* and a broad intraindividual and interindividual pharmacokinetic variability. Serious clinical consequences may occur because of under- or overdosing. Hence, individualization of calcineurin inhibitor dosage by therapeutic drug monitoring is required. When tacrolimus is utilized, a monitoring strategy based on trough levels is in general sufficient, because trough levels are good indicators of systemic exposure. In most transplant centers, doses are adjusted to attain target whole-blood trough concentrations of 8–12 μg/L during the first 3 months after transplantation, between 5 and 10 μg/L during month 4–12, and 4–8 μg/L thereafter. It must be emphasized that these target ranges are dependent on the concomitant immunosuppressive therapy. In the SYMPHONY trial, for example, low tacrolimus exposure (trough levels between 3 and 7 μg/L) in the first-year posttransplant in conjunction with MMF, prednisone, and daclizumab induction was associated with excellent efficacy and little tacrolimus-associated toxicity [46]. Therapeutic drug monitoring is required for individualization of dosage of ciclosporin. The traditional monitoring strategy for ciclosporin is based on pre-dose trough level measurements (C_0). One aims for the following trough levels in conjunction with MMF therapy and prednisone: Months 0 to 3 posttransplant: 120–200 μg/L, thereafter 80–160 μg/L. With the microemulsion formulation, ciclosporin levels at 2 h post-dose (C_2) have been found to correlate better with total drug exposure and immunosuppressive efficacy than C_0 levels [47–49]. A C_2 blood sample also has a higher proportion of parent drug when compared with a C_0 sample; this results in better agreement in C_2 levels measured by different assay methodologies than occurs with C_0 concentrations, which have a greater proportion of metabolites. However, error margins are greater for C_2 levels if the sample is not collected within a narrow (± 15 min) time window. Overall, C_2 monitoring has not been universally adopted.

Antiproliferative Agents

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) impairs lymphocyte function by blocking purine biosynthesis via inhibition of the enzyme inosine monophosphate dehydrogenase (IMPDH). MMF was developed as a replacement for azathioprine for maintenance immunosuppression. It is not nephrotoxic, and has less bone marrow toxicity than azathioprine. However, gastrointestinal toxicity can occur, usually manifested by gastritis and diarrhea. Mycophenolic acid (MPA), the active ingredient of the prodrug MMF, acts by blocking de novo purine synthesis in lymphocytes. Purines can be generated by de novo synthesis or by recycling (salvage pathway), and lymphocytes preferentially use the former. MPA is a selective and noncompetitive inhibitor of inosine monophosphate dehydrogenase 2 (IMPDH2), the rate-limiting enzyme in the de novo purine biosynthetic pathway for converting inosine monophosphate to guanosine monophosphate (GMP). Depletion of GMP by MPA has a relatively selective anti-proliferative effect on lymphocytes. In vitro, MMF blocks the proliferation of T and B cells, and inhibits clonal expansion. This results in inhibition of antibody production, generation of cytotoxic T cells, and development of delayed-type hypersensitivity. MPA is a more selective inhibitor of T- and B-cell proliferation than azathioprine due to greater dependence of lymphocytes on de novo synthesis of purines as compared to the "salvage" pathway. Furthermore, MPA impairs the ability of dendritic cells to present antigen, suppresses the recruitment of monocyte lineage cells, suppresses the glycosylation of adhesion molecules, inhibits vascular smooth muscle proliferation, improves endothelial function, and inhibits mononuclear cell recruitment into allografts and nephritic kidneys [50]. MPA also decreases cytokine-induced nitric oxide synthesis and prevents the formation of reactive species such as peroxynitrite. Furthermore, MPA exhibits antioxidant effects in experimental nephropathies. These properties of MPA likely augment its immunosuppressive properties by limiting fibrosis and vascular sclerosis after immunological injury [51].

MMF, a semisynthetic ethyl ester of MPA, is rapidly and completely absorbed and hydrolyzed by esterases to yield the active drug MPA. The *recommended dose* in pediatric patients in conjunction with ciclosporin is 1200 mg/m^2 per day in two divided doses, the recommended MMF dose in conjunction with tacrolimus is 600–800 mg/m^2 per day in two divided doses. However, data from a large prospective randomized study in both pediatric and adult renal transplant recipients on fixed dose MMF versus a concentration-controlled regimen, the FDCC study, indicate that a higher initial MMF dose, for example, 1800 mg MMF/m^2 per day in conjunction with ciclosporin and 1200 mg MMF/m^2 per day in conjunction with tacrolimus for the first 2–4 weeks posttransplant, is required to achieve adequate MPA exposure in the majority of patients [52, 53]. The MMF dose should be reduced with active CMV infection. When MMF is associated with diarrhea (a side effect of MMF, see below), dividing up the daily dosing to three to four doses per day may be effective in controlling the diarrhea.

The difference in MMF dosing depending on the concomitant calcineurin inhibitor is explained by a pharmacokinetic interaction of ciclosporin with the main MPA metabolite 7-O-MPA glucuronide (7-O-MPAG). Ciclosporin inhibits the multidrug resistance protein 2-mediated transport of 7-O-MPAG into the bile. MPAG is subject to enzymatic and nonenzymatic hydrolysis in bile and more importantly in the intestine, thereby liberating the unconjugated drug MPA, which is then reabsorbed into the systemic circulation. This enterohepatic circulation is responsible for a secondary MPA peak occurring six to 12 h after administration. The impact of the enterohepatic cycle on the MPA plasma concentration varies within and between individuals due to factors such as meal times or co-medication of drugs that interrupt the enterohepatic circulation (e.g., bile acid sequestrants and antibiotics). These factors should be considered when evaluating MPA concentrations (particularly pre-dose concentrations) in clinical practice. Furthermore, genetic abnormalities and disease can affect enterohepatic cycling and thus the bioavailability of MPA [54].

The metabolism of MPA due to glucuronidation can also be affected by drug induction. Glucocorticoids are known inducers of UDP-glucuronosyltransferases in vitro. When corticosteroids were completely withdrawn 12 months after transplantation, a 33% increase in the mean dose–normalized MPA pre-dose concentrations and MPA-AUCs was observed compared with concentrations at 6 months, when the patients were still receiving maintenance doses of steroids [55].

Following the success of the early MMF studies in adults, MMF was investigated in pediatric renal transplant recipients in open-label studies with historical controls. Data from three large multicenter studies [56–60] and one smaller study [61] provided support for the *safety and efficacy of MMF* in the pediatric renal transplant population when used with ciclosporin and prednisone. The incidence of acute rejection within the first 6–12 months for patients receiving MMF in these studies ranged from 28% to 37% [56, 58, 60]. Those studies comparing MMF patient groups to historical controls reported significant reductions in the incidence of acute rejection with MMF versus AZA [58, 60]. There was also a significant improvement in the incidence of acute rejection between patients receiving MMF and those receiving azathioprine at 3 years in a follow-up report to one study [59]. In one large study [56, 57], there were no differences in the incidence of acute rejection when the results were stratified by age. Medium-term (3-year) renal allograft and patient survival were excellent, with a 30% incidence of acute rejection [57]. MMF has a role in the prevention and/or treatment of chronic rejection. Among children with chronic rejection, some evidence suggests that substituting MMF for azathioprine may improve renal function [62, 63]. On the other hand, very long-term differences between MMF and azathioprine as anti-proliferative agents in at least in adult renal transplantation may be negligible [64], perhaps because azathioprine requires only once-daily dosing, which has been associated with improved adherence in particular in the setting of transition to adult care [65].

The major *toxicity of MMF* is gastrointestinal, mainly diarrhea, possibly as a result of the high concentrations of acyl-MPAG in the gut. In the MMF suspension trial in pediatric renal transplant recipients, safety of MMF was evaluated based on the occurrence of adverse events, including the development of opportunistic infections and malignancies. The most frequently noted adverse events were hematological problems such as leukopenia and gastrointestinal disorders such as diarrhea, which occurred in 25% and 16% of all patients, respectively, and were observed more often in the youngest age group. In general, the risk of developing side effects declines with increasing age. MMF is devoid of intrinsic renal, cardiovascular, or metabolic toxicities, but can increase the risk for CMV infections, leukopenia, and mild anemia (Table 3). MMF should not be used in pregnant transplant patients.

Patients on standard-dose MMF therapy show considerable between-patient variability in pharmacokinetic parameters. This variability is attributable to factors that influence exposure to MMF, such as renal allograft function, serum albumin levels, and use of concomitant medications such as ciclosporin that inhibit enterohepatic recirculation of the active metabolite of MMF, MPA, and genetic polymorphisms of MPA-metabolizing enzymes [54]. This variability is clinically relevant, as higher plasma concentrations of MPA are correlated with reduced risk of acute rejection after renal transplantation [66–68]. These findings have suggested that individualizing the dose regimen of MMF may further improve clinical outcomes compared with a standard-dose regimen.

There has been considerable debate regarding the utility of measuring MPA levels. Advocation for *MPA monitoring* is based on the premise that monitoring will result in avoiding both underdosing, which prevents rejection, and overdosing, which increases the risk of adverse reactions [67, 68]. One prospective randomized study in adults, for example, showed significantly fewer treatment failures and acute rejection episodes in the monitoring arm compared with the fixed-dose arm with no significant difference in side effects [69]. Within this study, MPA exposure and MMF dosing were higher in the monitoring arm based on three levels measured over the first 3 h post-dose (limited sampling strategy). Therefore, some transplant centers monitor MPA levels and target pre-dose levels between 1.5 and 4 mg/L. Some centers monitor MPA levels also as a measure of adherence to the immunosuppression plan. In general, monitoring of MPA exposure by MPA pre-dose plasma levels is more popular in clinical practice than monitoring of the area under the concentration time curve (MPA-AUC), for example, by a *limited sampling strategy*, but less precise. An MPA-AUC > 40 mg × L/12 h has been recommended for sufficient MPA exposure for the prevention of acute rejection episodes [68]. However, AUC monitoring, while being more accurate, is also more cumbersome and expensive.

Azathioprine

Azathioprine is a purine analogue derived from 6-mercaptopurine (6-MP), which has been widely used in renal transplantation for four decades, but is now substituted by the more efficacious MMF in most transplant centers. Azathioprine is metabolized in the liver to 6-MP and further converted to the active metabolite thioinosinic acid (TIMP) by the enzyme hypoxanthine–guanine phosphoribosyltransferase. Some but not all the immunosuppressive activity of azathioprine is attributable to 6-MP. Azathioprine acts mainly as an antiproliferative agent by interfering with normal purine pathways, by inhibiting DNA synthesis, and by being incorporated itself into DNA, thereby affecting the synthesis of DNA and RNA [70]. By inhibiting the synthesis of DNA and RNA, azathioprine suppresses the proliferation of activated B and T lymphocytes. In addition, azathioprine has been shown to reduce the number of circulating monocytes by arresting the cell cycle of promyelocytes in the bone marrow.

Thiopurine methyltransferase (TPMT) enzyme activity is a major factor determining azathioprine and 6-MP metabolism, and therefore 6-thioguanine (6-TG) and 6-methylmercaptopurine (6-MMP) levels. Approximately 89% of the population has wild-type TPMT, which is associated with normal or “high” TPMT enzyme activity, while 11% are heterozygous and have corresponding low TPMT enzyme activity. Most importantly, 0.3% of the population is homozygous for mutations of TPMT and thus have negligible activity, which causes 6-MP to be preferentially metabolized to produce high levels of 6-TG, which then leads to bone marrow suppression. Intermediate and normal metabolizers can have up to a threefold difference in initial target doses of azathioprine and 6-MP to achieve therapeutic 6-TG concentrations. We suggest obtaining both thiopurine methyltransferase (TPMT) genotype and TPMT enzyme activity (phenotype) testing in all patients who are evaluated for treatment with azathioprine or 6-mercaptopurine (6-MP). Genotype testing is suggested by the manufacturer and the US Food and Drug Administration.

Azathioprine is administered orally at 1.5 mg/kg per day (45 mg/m^2 body surface area per day) in conjunction with calcineurin inhibitors and 2.5 mg/kg per day, when used without calcineurin inhibitors. It is metabolized in the liver to 6-MP and further converted to the active metabolite TIMP. As 6-MP is degraded by xanthine oxidase, allopurinol (a xanthine oxidase inhibitor) will increase the levels of TIMP. Severe leukopenia can occur if allopurinol (used for the treatment of hyperuricemia and gout) is given with azathioprine, so allopurinol should generally be avoided in patients treated with azathioprine. The major side effect of azathioprine is bone marrow suppression. All three hematopoietic cell lines can be affected, leading to anemia, leukopenia, and thrombocytopenia. The hematologic side effects are dose related and can occur late in the course of therapy. They are usually reversible upon dose reduction or temporary discontinuation of the drug. Azathioprine should be temporarily withheld if the white cell count falls below 3000/mm^3 or if the count drops by 50% in consecutive checks. Recovery usually occurs within 1–2 weeks and then azathioprine can be restarted at a lower dose and increased gradually to the usual maintenance dose while monitoring the white cell count. Hepatotoxicity is another potentially serious side effect of azathioprine, which requires decreasing the dose or even discontinuation. Azathioprine has also been linked to the development of skin cancer, the most common malignancy in renal transplant recipients. As a result, patients taking azathioprine for a prolonged period should be instructed to avoid direct exposure to sunlight or to use heavy sun screens when exposed. However, other immunosuppressants also contribute to the increased skin cancer risk in transplant recipients [71, 72]. The recommendations to minimize sun exposure are therefore not azathioprine specific. Other side effects of azathioprine include increased susceptibility to infection and hair loss.

The Target of Rapamycin (TOR) Inhibitors Everolimus and Sirolimus

Sirolimus (rapamycin) is a macrocyclic triene antibiotic that is produced by the actinomycete *Streptomyces hygroscopicus*. Sirolimus was approved in September 1999 by FDA and in December 2000 by the European Medicines Agency for use in adult renal transplant recipients. Everolimus is an analogue of sirolimus that has similar effectiveness and side effect profile as sirolimus, but different pharmacokinetics (shorter half-life). Everolimus and sirolimus are both macrolide derivatives and share many pharmacokinetic features, including a close correlation between total exposure and trough concentration, low absorption that varies between and within patients, and differences in absorption between adults and children [73, 74]. Everolimus is the 40-O-(2-hydroxyethyl) derivative of sirolimus, a modification that results in some important pharmacokinetic differences between the two drugs. Everolimus is more hydrophilic than sirolimus and is absorbed more rapidly from the gut with more systemic clearance than sirolimus [75]. As a result, the elimination half-life of everolimus is shorter than for sirolimus (mean 28 h versus 62 h) [76, 77]. The clinical effect is that no loading dose is required for everolimus and that it is administered twice a day both in adults in children. There are more data available on the use of everolimus than sirolimus in pediatric renal transplantation.

Everolimus displays a novel mechanism of immunosuppressive action, which is distinct from that of the other immunosuppressive drugs. Everolimus first binds to the cytosolic immunophilin FK-binding protein 12 (FKBP12). This complex binds to and inhibits the activation of the mammalian target of rapamycin (mTOR), a key regulatory kinase. This inhibition suppresses cytokine-mediated T cell proliferation inhibiting the progression from the G1 to the S phase of the cell cycle. Thus, everolimus acts at a later stage in the cell cycle than do the calcineurin inhibitors ciclosporin and tacrolimus. Everolimus can, therefore, be used in combination with the calcineurin inhibitors to produce a synergistic effect [78].

Everolimus is available as tablets and dispersible tablets for administration in water. The current evidence from pediatric renal transplantation suggests that everolimus be administered at an initial dose of 0.8 mg/m^2 body surface area twice daily when given in combination with ciclosporin therapy, adjusted to target a trough concentration of 3–8 μg/L [79, 80]. There is a well-documented drug-drug interaction between mTOR inhibitors and ciclosporin [74], arising from a shared metabolic pathway (via the cytochrome P450 CYP3A4 isoenzyme system) and the fact that both are substrates for the drug transporter P-glycoprotein. Everolimus exposure is increased by up to threefold in patients receiving concomitant ciclosporin

[81, 82], while tacrolimus exerts only a minimal effect [82, 83]. In patients receiving everolimus with concomitant tacrolimus, a dose of 2 mg/m^2 body surface area twice daily is therefore appropriate [81].

The most frequent reason to include an mTOR inhibitor in the immunosuppressive regimen is to facilitate a reduction in calcineurin inhibitor exposure, or to eliminate calcineurin inhibitor therapy entirely. The current evidence suggests that de novo administration of everolimus with low-exposure calcineurin inhibitor therapy in children undergoing renal transplantation is efficacious and safe. The recently published 36-month, multicenter, open-label randomized study investigated everolimus with reduced-dose tacrolimus and corticosteroid elimination from month 5 posttransplant compared with a standard-dose tacrolimus regimen with MMF and corticosteroids (control) [84]. The incidence of composite efficacy failure (biopsy-proven acute rejection [BPAR], renal allograft loss, or death) at month 36 was 9.8% versus 9.6% for everolimus with reduced-dose tacrolimus and MMF with standard-dose tacrolimus, respectively, which was driven by BPARs. Renal allograft loss was low (2.1% versus 3.8%) with no deaths. Mean estimated glomerular filtration rate at month 36 was comparable between groups. Growth in pre-pubertal patients on everolimus with reduced-dose tacrolimus without glucocorticoids was better ($p = 0.05$) versus MMF with standard-dose tacrolimus and glucocorticoids. The overall incidence of adverse events and serious adverse events was comparable between groups. Rejection was the leading adverse event for study drug discontinuation in the everolimus with reduced-dose tacrolimus group. The authors concluded that, although adverse events–related study drug discontinuation was higher, an everolimus with reduced-dose tacrolimus regimen represents an alternative treatment option that enables withdrawal of corticosteroids as well as reduction of calcineurin inhibitors for pediatric renal transplant recipients [84].

Use of de novo everolimus with complete calcineurin inhibitor avoidance has not been explored in large trials in pediatric transplant recipients, but is unlikely to be preferable to concomitant reduced-exposure calcineurin inhibitor. Switching maintenance patients to an mTOR inhibitor to facilitate calcineurin inhibitor minimization can improve renal allograft function or avoid further functional deterioration, particularly when undertaken before irreversible damage has developed. Late switch below an eGFR of 40 mL/min/1.73 m^2, however, may be associated with an increase in preexisting proteinuria due to podocytopenia, favoring early conversion. It remains unresolved whether calcineurin inhibitor therapy should be reduced or, indeed, eliminated in maintenance patients regardless of whether renal dysfunction is believed to be due to calcineurin inhibitor–related nephrotoxicity. Currently, many transplant centers use mTOR inhibitors as part of a maintenance immunosuppressive regimen only in the following patient subsets in which this drug class may have particular utility: (i) In patients who have histologically proven calcineurin inhibitor nephrotoxicity despite low levels and doses of the calcineurin inhibitor; (ii) in patients with malignancy (e.g., skin cancers and Kaposi sarcoma), either in remission or being actively treated; (iii) after treatment of B cell PTLD; and (iv) in patients with recurrent CMV viremia, because everolimus has anti-CMV activity in vitro and is associated with less CMV replication and disease in vivo compared to MMF [85, 86]. Notably, the incidence of Epstein-Barr virus (EBV) or BK polyomavirus infection is not lower in everolimus- compared to MMF-treated patients [84].

Clinically relevant *adverse effects* of everolimus that require a specific therapeutic response or can potentially influence short- and long-term patient morbidity and mortality as well as renal allograft survival include hypercholesterolemia, hypertriglyceridemia, infectious and noninfectious pneumonia, anemia, lymphocele formation, and impaired wound healing (Table 3). There continues to be concern regarding male fertility in the setting of mTOR inhibition [87], and primarily mTOR-based, calcineurin inhibitor–free immunosuppression is associated with a significantly increased risk for the development of donor-specific antibodies [88]. These drug-related adverse effects are important determinants in the choice of a tailor-made immunosuppressive drug regimen that complies with the individual patient risk profile. Equally important in the latter decision is the lack of severe intrinsic nephrotoxicity associated with everolimus and its advantageous effects on arterial hypertension, posttransplantation diabetes mellitus, and esthetic changes induced by calcineurin inhibitors. Mild and transient thrombocytopenia, leukopenia, gastrointestinal adverse effects, and mucosal ulcerations are all minor complications of everolimus therapy that have less impact on the decision for choosing this drug as the basis for tailor-made immunosuppressive therapy.

Glucocorticoids

Glucocorticoids, developed in the early 1950s, represent one of the principal agents used for both maintenance immunosuppression and treatment of acute rejection. Glucocorticoids have both anti-inflammatory and immunosuppressive actions [89]. Lymphopenia and monocytopenia occur with the inhibition of lymphocyte proliferation, survival, activation, homing, and effector functions. The major glucocorticoids used are prednisone or prednisolone (given orally with comparable efficacy) and methylprednisolone (given orally or intravenously with 25% more potency). These agents are rapidly absorbed and have short plasma half-lives (60–180 min), but long biological half-lives (18–36 h).

In many transplant centers, the initial dose of glucocorticoids is usually administered during surgery as intravenous methylprednisolone, at doses between 2 and 10 mg/kg body weight. The oral dose of glucocorticoids used for maintenance therapy varies between 15 and 60 mg/m^2 per day (0.5–2 mg/kg body weight per day), which is gradually tapered over time to approximately 3–5 mg prednisone per m^2 body surface area, usually taken as a single morning dose. Alternate-day dosing is often administered 6–12 months posttransplant to minimize the effect of glucocorticoids on growth.

Glucocorticoids have multiple side effects in children, including growth impairment, susceptibility to infections, Cushingoid appearance, body disfigurement, acne, cardiovascular complications, arterial hypertension, hyperglycemia, aseptic bone necrosis, osteopenia, cataracts, poor wound healing, and psychological effects (Table 3). These negative impacts on appearance may play a role in poor adherence, especially in the body image–conscious adolescents. The risk for infection is excessive if high-dose pulse therapy is prolonged (typically >3 g/1.73 m^2). Glucocorticoid dosage should, therefore, be decreased gradually during rejection treatment, even if serum creatinine fails to improve. Interestingly, glucocorticoids are not associated with increased risk for malignancy. One of the most important reasons for stopping corticosteroids or switching to alternate-day therapy is growth impairment, which is frequently observed in those on continuous treatment.

Due to the multiple adverse effects of maintenance glucocorticoid (steroid) therapy, attempts have been made to withdraw or minimize them in children with a renal allograft [90–96]. There are two major approaches in steroid minimization in pediatric renal transplantation: (i) late steroid withdrawal (>1-year posttransplantation) and (ii) either complete steroid avoidance or early steroid withdrawal (<7 days posttransplantation). In the late steroid withdrawal approach, the patients suitable for minimization are identified by stable posttransplant clinical course and renal allograft function. In late steroid withdrawal, there is no need for an antibody induction in the perioperative period [94, 95]. In early withdrawal or complete avoidance protocols, the criteria of suitability are predefined before transplantation (e.g., criteria of low immunological risk) and antibody induction is used in all enrolled patients [22, 96–100]. There is also an “intermediate” approach, combining elements from early and late withdrawal protocols, in which antibody induction is used; however, the decision of corticosteroid withdrawal is delayed until 6–9 months posttransplant, when stable renal graft function (sometimes combined with normal picture of protocol biopsy) allows to identify suitable candidates (as in the late withdrawal approach) [84, 101]. Although some hypothesize that corticosteroid withdrawal has the advantage over corticosteroid avoidance and that immunologically high-risk patients and those with unstable renal allograft function can easily be identified beforehand and be excluded from corticosteroid-free immunosuppression, others support that corticosteroid avoidance avoids the conditioning of the immune response to chronic corticosteroid exposure and may more likely to be successful and have lower immune risk than corticosteroid withdrawal, where an immune system, primed to chronic corticosteroids, now "rebounds" and develops acute rejection during the withdrawal period [102].

Corticosteroid avoidance may eventually be found to provide the best overall risk-to-benefit ratio with maintenance immunosuppressive therapy in renal transplantation. Corticosteroid avoidance protocols have been used successfully and have undergone extensive evaluation both in the USA and in Europe. However, many of these protocols have chosen low-risk individuals and utilized intensive induction therapy with thymoglobulin, tacrolimus, and MMF. Regarding the efficacy and safety of early corticosteroid withdrawal or complete corticosteroid avoidance, a randomized controlled study in 196 pediatric renal transplant recipients, two doses of daclizumab in patients treated with a regimen of tacrolimus and MMF allowed early steroid withdrawal on day five posttransplant [98]. There was a comparable rate of biopsy-proven acute rejection rates after 6 months in patients of corticosteroids compared with controls (10.2% versus 7.1%). In addition, pre-pubertal patients with early corticosteroid withdrawal showed better growth and lipid and glucose metabolism profiles compared with controls, without increases in renal allograft rejection or loss. These favorable effects were confirmed in a follow-up study over a 2-year observation period [99]. The results of the North American randomized controlled multicenter study with a follow-up of 3 years posttransplant showed that the corticosteroid-free group showed lower systolic blood pressure and lower cholesterol levels [100]. The authors concluded that complete corticosteroid avoidance is safe and effective in nonsensitized children receiving primary renal transplants [100]. Many centers now opt to utilize complete corticosteroid avoidance in the unsensitized, low-risk pediatric recipients, with 3–5 days of thymoglobulin with the recent corticosteroid-free protocol that only utilizes corticosteroids for the thymoglobulin premedication [103]. The corticosteroid avoidance regimen also provides some benefit for reducing subclinical and clinical herpes viremia, which has a positive impact for both reducing recipient morbidity from infection and improving allograft function and reducing anti-donor HLA responses [104].

Nevertheless, corticosteroid withdrawal or avoidance following renal transplantation remains a center-specific choice based on local experience with either regimen. Although the benefits of using corticosteroid-free protocols in pediatric patients shows great promise, further study is needed to determine the impact to identify new monitoring tools to assess the immunologic safety for patients who can be successfully converted to later posttransplant corticosteroid-free immunosuppression after having initially started a corticosteroid-based maintenance immunosuppression protocol, without increasing the risk of acute rejection.

Generic Immunosuppressive Drugs

In the field of solid organ transplantation, the number of immunosuppressive drugs prescribed to prevent rejection is relatively small. Not more than 10 different compounds have been used over a period of 50 years. For most of these drugs the patents have expired (azathioprine, ciclosporin, tacrolimus, mycophenolate mofetil, and sirolimus), or will expire within the next few years (everolimus and mycophenolate sodium) [105]. Policymakers consider generic drugs an attractive option to enable savings on medication cost, allowing the savings to be used for funding high-cost medicines. Generic immunosuppressive drugs are available in Europe, Canada, and the USA. Between countries, there are large differences in the market penetration of generic drugs in general, and for immunosuppressive drugs in particular. To allow for safe substitution, a number of criteria need to be fulfilled. Generic substitution should not be taken out of the hands of the treating physicians. Generic substitution can only be done safely if initiated by the prescriber, and in well-informed and prepared patients. Payers should refrain from forcing pharmacists to dispense generic drugs in patients on maintenance treatment with innovator drug. Instead, together with transplant societies, they should design guidelines on how to implement generic immunosuppressive drugs into clinical practice. Substitutions must be followed by control visits to check if the patient is taking the medication correctly and if drug exposure remains stable. Inadvertent, uncontrolled substitutions from one generic to another, initiated outside the scope of the prescriber, must be avoided as they are unsafe. Repetitive subsequent generic substitutions result in minimal additional cost savings and have an inherent risk of medication errors [105].

Adherence to Immunosuppressive Medication

Adherence to medications is defined as the process by which patients take their medication as prescribed. Adherence is of critical importance and it is often lacking, especially in teenagers. Adolescent age at transplant is an independently significant risk factor for worse long-term renal allograft survival in all major pediatric solid organ transplant types [106]. Adolescents have also been identified to have a multitude of psychiatric and socioeconomic risk factors that are deserving of greater attention and customized care delivery programs [107]. Immunosuppression obviously only works if it is taken reliably, and there is ample evidence in the literature that this reliability is lacking far too often and that such lack is leading to adverse outcomes. Moreover, immunosuppressive regimens may need to be adjusted to support adherence, for example, by combination products to reduce the pill burden and/or by once daily dosing. For example, there is a prolonged-release tacrolimus formulation available for older children and adolescents (Advagraf™ in Europe and Astagraf™ in the USA). Comparative pharmacokinetic studies have shown that stable pediatric transplant recipients can be converted from immediate-release to prolonged-release-tacrolimus at the same total daily dose, using the same therapeutic drug monitoring method [108, 109].

Diagnosis and Management of Allograft Rejection

The renal allograft, during its lifetime, is at continuous risk for the development of rejection due to HLA and non-HLA incompatibility with the recipient. Allograft rejection has been historically classified as hyperacute, acute, and chronic.

Hyperacute Rejection

Hyperacute rejection (HAR) can occur due to preformed donor-specific antibodies against HLA antigens, antibodies to ABO blood group antigens, or rarely to other minor HLA and tissue antigens [110]. Immediately upon grafting, these antibodies bind to the vascular endothelium causing complement-mediated endothelial injury, resulting in vascular clotting and renal allograft loss. Histologically, there is glomerular thrombosis, fibrinoid necrosis, polymorphonuclear leukocyte infiltration, and intra-graft hemorrhage. HAR existed in the early era of transplantation, when the HLA matching and cross-match techniques were less well developed. It has been nearly eliminated with flow-based sensitive cross- match assays and precise pre-transplant characterization of anti HLA antibodies, avoiding transplants with antigens against which these antibodies are directed.

Acute Rejection

Acute rejection denotes acute allograft dysfunction due to immune-mediated injury and generally occurs within 1 week and 6 months of transplantation, although it can occur at any time in the face of lower-maintenance immunosuppression. Advances in immunosuppressive therapy have drastically improved acute allograft rejection rates to less than 15% in the first year of transplant

[111]. Depending upon the timing of acute rejection in relation to transplant, it may be arbitrarily classified as early acute rejection (EAR) which can happen within first-year posttransplant and late acute rejection that can happen any time after that. Rates of acute rejection remain high in adolescents and young adults attributed mainly to nonadherence with the maintenance immunosuppressive therapies [112]. Acute rejection episodes may also occur when there is aggressive reduction of immunosuppression in response to viral replications such as EBV/BKV or due to calcineurin inhibitor (CNI) minimization strategies. In the modern era, there is decreased prevalence of early acute rejections due to potent induction and maintenance immunosuppression, whereas late acute rejection rates are increasing [113].

Risk factors: An individual's immunologic risk for acute rejection is attributed to overall level of HLA mismatch with the donor and presence of donor-specific anti-HLA antibodies. Repeat transplants, black race, recipient age, and delayed graft function are additional risk factors. HLA mismatch with the donor and presence of donor-specific antibodies (DSA) are the main predictors of acute T-cell-mediated cellular rejection (ATCR) and acute antibody-mediated rejection (ABMR), respectively. HLA epitope matching, especially for DR and DQ loci, is being investigated to improve immunological matching between donor and recipients and to decrease long-term risk of de novo DSA formation, ABMR, and improve renal allograft outcomes [114, 115]. Approximately 30–50% of patients with pre-transplant DSA undergoing desensitization may experience ABMR [116]. Delayed graft function has been shown to increase the risk for early acute rejection in several adult studies [117]. The single most important risk factor for late acute rejection in primary transplant recipients is nonadherence with immunosuppression, especially if combined with a high degree of HLA or epitope mismatch [118]. High coefficient of variation, expressed in percentage (%) (defined as SD /mean ×100), of tacrolimus trough levels has been correlated with an increased incidence of acute rejection and used as a marker of nonadherence [119, 120].

Clinical features: Acute rejection should be suspected when there is acute renal allograft dysfunction, manifested as an increase in serum creatinine. This increase is arbitrary and an increase of serum creatinine by 0.3 mg/dL or >15–25% increase over baseline is considered significant. The increase in serum creatinine may not occur in young children until into the late stage of acute rejection due to high nephron mass in a child with an adult-sized kidney. Other features of acute rejection may include allograft pain and tenderness, oliguria, hematuria, hypertension, and proteinuria. However, the majority of children with acute rejection are asymptomatic.

Differential diagnosis: Conceptually, acute allograft dysfunction is akin to acute kidney injury (AKI) occurring in a transplant kidney. Differences from AKI in native kidneys include unique characteristics of transplant. The transplanted kidney is a single kidney that has gone through implantation process, and is HLA incompatible with the recipient who is receiving chronic immunosuppression with nephrotoxic calcineurin inhibitor (CNI) medications. Therefore, differential diagnosis of acute allograft dysfunction includes pre-renal and post-renal causes, AR, CNI toxicity, and infections (Table 4). Sometimes, drugs that interfere with creatinine excretion such as sulphamethoxazole-trimethoprim and ciprofloxacin may also cause an increase in serum creatinine and should be considered in differential diagnosis.

Diagnosis: Laboratory studies may show an increase in serum creatinine, proteinuria, hematuria, and/or leukocyturia. Radiographic studies are nonspecific for the diagnosis but would help exclude other causes of allograft dysfunction such as obstruction to urine flow or urinary leak. Doppler renal ultrasound will help evaluate perfusion of the transplant kidney and would rule out any renal arterial or venous thrombosis (rare outside immediate posttransplant period). Otherwise, ultrasound findings of acute rejection are nonspecific and may include increased allograft size, loss of cortico-medullary differentiation, and elevated resistive indices on Doppler. Nuclear medicine scans including MAG-3 renography may demonstrate rapid uptake of the tracer but delayed

Table 4 Differential diagnosis of acute allograft dysfunction

Pre-renal
Dehydration, low BP Renal arterial/venous thrombosis (rare outside immediate post-op period)
Renal
Acute rejection, CNI toxicity Infections: APN, BKV, CMV and adenovirus[a] Recurrent diseases: FSGS, aHUS, C3GN, primary hyperoxaluria, IGAN[a], ANCA+ GN[a], anti GBM disease[a], De novo diseases: FSGS, Membranous GN
Post-renal:
UPJ or UVJ obstruction, perirenal hematoma or fluid, stent obstruction or dislodgement Bladder dysfunction
Risk factors for chronic allograft dysfunction
Immune factors: Chronic active TCMR (HLA A, B, DR mismatch or high epitope mismatch load) Chronis active ABMR (donor specific antibodies, antibodies to ATII type I receptor, anti- endothelial cell antibodies, MICA antibodies and rarely other autoantibodies)
Non-Immune factors:
Donor factors (age, race, size, cause of death) Transplant related factors (ischemia reperfusion injury) Chronic CNI toxicity, chronic viral infection (BKV), Recurrent pyelonephritis Recurrent obstructions (UPJ or UVJ obstruction or bladder dysfunction) Recipient factors (High BMI, hypertension, proteinuria, diabetes, dyslipidemia and rarely chronic hypoperfusion in young children due to low blood pressure) Recurrent diseases (FSGS, aHUS, C3GN, hyperoxaluria)

Abbreviations: *aHUS* atypical hemolytic uremic syndrome, *ABMR* antibody mediated rejection, *ANCA* antineutrophilic cytoplasmic autoantibody, *APN* acute pyelonephritis, *BKV* BK virus infection, *CMV* cytomegalovirus, *C3GN* C3 glomerulonephritis, *CNI* calcineurin inhibitors, *EBV* Epstein Barr virus, *FSGS* focal segmental glomerulosclerosis, *GBM* glomerular basement membrane, *GN* glomerulonephritis, *IGAN* IgA nephropathy, *MICA* minor histocompatibility chain A, *TCMR* T-cell-mediated rejection, *UPJ* ureteropelvic junction, *UVJ* ureterovesical junction

[a] Rare

cortical function and no obstruction to urine flow. Radionuclide scans and ultrasounds cannot distinguish among various causes of graft dysfunction, such as rejection, acute tubular necrosis, CNI toxicity, and viral nephropathies. Other tests such as CNI levels, COV% of tacrolimus trough levels, urinalysis and culture, and blood BK DNA viral load may give clues to the differential diagnosis.

Renal allograft biopsy remains the gold standard diagnostic procedure. In addition to confirming the presence or absence of acute rejection, histopathology allows evaluation for the two main forms of acute rejection: ACR and ABMR. As the mechanisms and therapies for ACR and ABMR differ, the importance of defining the underlying pathology cannot be understated. Of note, distinguishing between severe ACR and ABMR can be challenging, and both may coexist especially in LAR. Allograft histology is interpreted using the Banff classification which has undergone extensive updating and revisions [121, 122].

Acute Cellular Rejection

Histopathology of ACR is characterized by interstitial infiltration with mononuclear cells and tubulitis (disruption of the tubular basement membrane by infiltrating cells), and intimal arteritis (subendothelial infiltration of mononuclear cells). Occasional eosinophils and plasma cells may be present, though predominance of eosinophils may be suggestive of interstitial nephritis. Areas of patchy interstitial inflammation without evidence of tubulitis are not uncommon and are insufficient to support diagnosis of ACR. The presence of significant number of neutrophils may suggest pyelonephritis or ABMR. Banff classification of ACR defines this into borderline, grade I A and 1B, depending upon the area of interstitial inflammation and severity of tubulitis

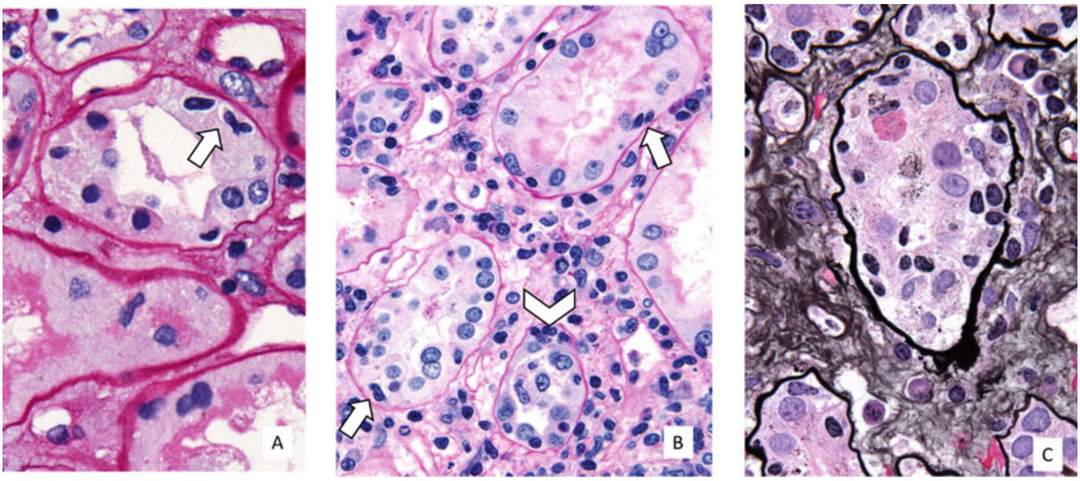

Fig. 3 Acute T-cell-mediated rejection. (**a**) Mild tubulitis with 1–4 lymphocytes (arrow) in a tubular wall. (PAS) (**b**) Interstitial inflammation with mild (arrows) and moderate (5–10 lymphocytes/10 tubular cells, chevron) tubulitis, Banff grade 1A. (PAS) (**c**) Severe tubulitis with >10 lymphocytes/10 tubular cells, Banff grade 1B. (Jones silver stain). (Courtesy, Dr. Cynthia Nast, Cedars-Sinai Medical Center, LA, CA)

(Fig. 3) and into grade 2A, 2B, and 3 depending upon the involvement and severity of arteritis (Table 5).

Acute Antibody-Mediated Rejection

ABMR may occur due to formation of de novo DSA after transplant or due to preexisting DSA in patients undergoing desensitization and rarely due to other antibodies. These antibodies interact with endothelial cells of glomerular and peritubular capillaries (PTC) and may cause complement-mediated or antibody-dependent cytotoxic damage depending upon the strength and characteristics of antibodies. The Banff classification of acute ABMR continues to evolve with recognition of its variable histologic presentation. The diagnosis of acute ABMR depends upon the presence of all three criteria (histologic evidence of injury, current/recent interaction of DSA with the endothelium, and serologic presence of DSA) shown in Table 5. Histologic changes include presence of either acute tubular injury or glomerulitis and peritubular capillaritis or intimal arteritis or thrombotic microangiopathy without an apparent cause. Current/recent interaction of DSA with the endothelium includes presence of C4d (complement 4 split product) deposited in PTC demonstrated by immunofluorescence or immunoperoxidase or presence of moderate microvascular inflammation or gene transcripts of endothelial activation (Fig. 4). Though C4d-positive ABMR may represent a more severe form, the sensitivity of C4d is low due to its focal presence and dependency on the PTC for expression and ability of DSA to bind complement. Studies have established the existence of C4d-negative ABMR. Therefore, C4d staining is no longer a requirement for the diagnosis of ABMR and has been substituted with either presence of endothelial cell transcripts (not widely available) or presence of moderate microvascular inflammation [121].

Noninvasive Biomarkers of Acute Rejection

Noninvasive monitoring of blood and urine for prediction of acute rejection and graft injury is being investigated by using gene expression panels, immune repertoire sequencing [123, 124], transcriptomes [125], proteomes [126], and donor-derived cell-free DNA in blood [127–129]. In addition, a recent publication this year identified a composite panel of cell-free DNA, methylated cell-free DNA, CXCL10, clusterin, protein, and creatinine in urine [127], to result in a composite risk score (Q-Score) to classify biopsy-confirmed ACR and ABMR in both adult and children with high levels of accuracy [130–132]. These

Table 5 Histologic diagnosis of acute allograft rejection according to Banff 2017

Acute T cell–mediated rejection (TCMR)
Ia >25% Interstitial inflammation with moderate tubulitis (t2)
Ib >25% Interstitial inflammation with severe tubulitis (t3)
IIa Mild-to-moderate intimal arteritis (v1)
IIb Severe intimal arteritis (v2)
III Transmural arteritis and/or fibrinoid necrosis (v3)
Acute antibody-mediated rejection (ABMR): Should have all three criteria below
Histologic evidence of tissue injury:
Acute tubular injury
Microvascular inflammation ($g > 0$ and/or $ptc > 0$)
Arteritis ($v > 0$)
Thrombotic microangiopathy without apparent cause
Evidence of current/recent antibody interaction with endothelium:
Positive C4d staining of peritubular capillaries
Moderate microvascular inflammation ($g + ptc \geq 2$)
Increased expression of gene transcripts in biopsy tissue strongly associated with ABMR
Serologic evidence of donor-specific antibodies (DSA)
Positive C4d staining/ presence of ABMR-associated gene transcripts may substitute for DSA

i0 – No inflammation or in <10% of unscarred cortical parenchyma. i1 – Inflammation in 10–25% of unscarred cortical parenchyma. i2 – Inflammation in 26–50% of unscarred cortical parenchyma. i3 – Inflammation in more than 50% of unscarred cortical parenchyma

t0 – No mononuclear cells in tubules or single focus of tubulitis only, t1 – Foci with 1–4 mononuclear cells/tubular cross section (or 10 tubular cells), t2 – 5–10 mononuclear cells and t3 – Foci with >10 mononuclear cells/tubular cross section or the presence of ≥2 areas of tubular basement membrane destruction accompanied by i2/i3 inflammation and t2 elsewhere

G: glomerulitis, none (g0), segmental or global glomerulitis in 75% of glomeruli (g3), PTC: peritubular capillaries- at least 1 leukocyte in ≥10% of cortical PTC but 10 leukocytes in most severely involved PTC (ptc3)

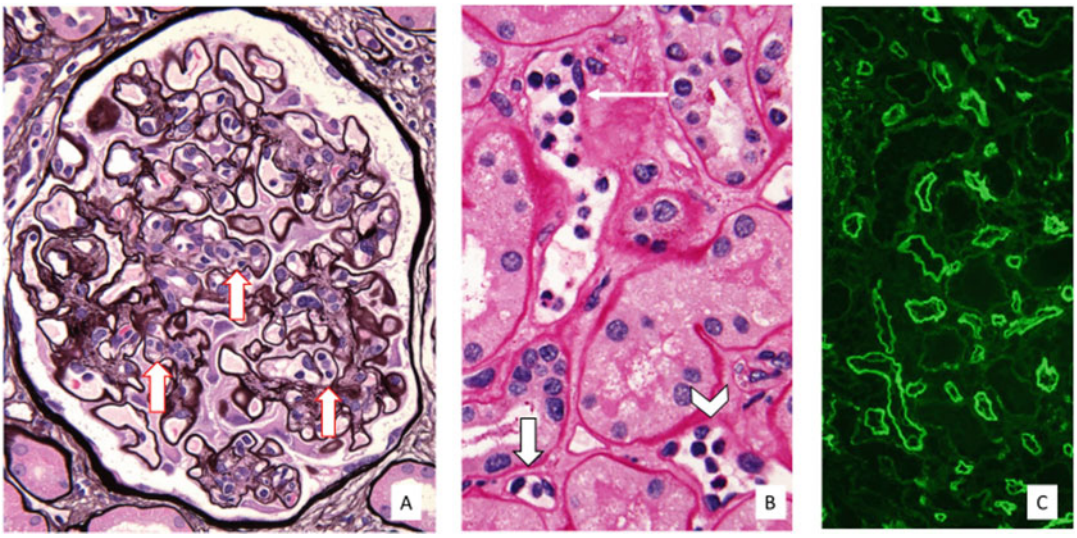

Fig. 4 Active antibody mediated rejection. (**a**) Leukocytes, predominantly monocytes, and swollen endothelial cells(arrows) are within and occluding glomerular capillary lumens (glomerulitis). (Jones silver) (**b**) Leukocytes and swollen endothelial cells in peritubular capillary lumens (peritubular capillaritiis). Mild (3–4 cells, thick arrow); moderate (5–10 cell, chevron); severe (>10 cells, thin arrow). (PAS) (**c**) Immunofluorescence for C4d showing linear staining of peritubular capillary walls. (Courtesy, Dr. Cynthia Nast, Cedars-Sinai Medical Center, LA, CA)

biomarkers are being currently studied in children to pave the way over time to early and noninvasive diagnosis of acute rejection in the near future [133].

Therapy

Treatment strategies depend upon whether ACR, acute ABMR, or mixed acute rejection is present. Aggressiveness of treatment generally follows severity of lesions. Graft prognosis after treated acute rejection also depends on type and severity; however, any untreated clinical acute rejection episode will ultimately result in accelerated graft loss. Thus, timely diagnosis is crucial to promptly initiate appropriate treatment.

Standard initial treatment of ACR is intravenous methylprednisolone (10 mg/kg body weight, maximum dose, 0.5–1.0 g) as a single daily dose for 3–5 days. Majority of Banff class 1 lesions respond to methylprednisolone alone. This is typically followed by the intensification of oral prednisone (i.e., 2 mg/kg/daily) and subsequent taper to pre-rejection dosage [134]. For children who are on steroid-free immunosuppression prior to acute rejection, it may be reasonable to stop prednisone. However, if episodes of rejection prove to be recurrent or DSA is detected, continuation of low-dose-maintenance steroids may be needed. If renal function does not improve after 5 days of intravenous glucocorticoids, steroid-resistant rejection should be considered.

Steroid-resistant acute ACR and Banff II and III lesions generally require T cell–depleting therapy, most commonly rabbit antithymocyte globulin (rATG) dosed at 1.5 mg/kg for five to seven doses. A randomized, controlled trial showed superior efficacy of rATG over horse antithymocyte globulin [135]. Cochrane Database review in 2017 concluded that antibody therapy was superior to steroid therapy in reversing T cell–mediated rejection with no effect on subsequent acute rejections [136]. There are scant pediatric data to guide dosing. Data using alemtuzumab for treatment of acute rejection are limited but suggest efficacy [137]. Lymphocyte depleting antibodies often produce cytokine release effects including fever and chills. Methylprednisolone, antihistamines, and acetaminophen are used to decrease these side effects. Due to potent immunosuppressive effect of rATG, there is concern for increased risk of infection and lymphoproliferative disorder [138]. Posttreatment viral monitoring and prophylaxis against cytomegalovirus and pneumocystis jirovecii should be provided until lymphocytes recover to the reference range, usually for 4–6 months.

The treatment of acute ABMR is much less efficacious and aims of treatment are threefold: (1) to remove existing alloantibodies, (2) to prevent damage being caused by existing alloantibodies, and (3) to prevent ongoing production of alloantibodies. Therapeutic approaches include combinations of plasmapheresis, immunoadsorption, intravenous immunoglobulin G (IVIG), anti-lymphocyte therapies, and adjustment of baseline immunosuppression. Many other experimental therapies have been tried in small studies.

Treatments of ABMR trials are small with large degrees of heterogeneity including patients with both acute and chronic lesions [139]. There is low-quality evidence supporting plasma exchange, and very-low-quality evidence for all other treatments. Nevertheless, plasma exchange and IVIG, with or without B cell depletion with intravenous rituximab, is the most used strategy for ABMR. A typical regimen includes daily or every other day plasma exchange consisting of 1.5 plasma volume removals with each treatment followed by IVIG at 100–200 mg/kg, with or without a single dose of rituximab at 375 mg/m^2. Immunoadsorption is no longer available in the USA.

IVIG is shown to be beneficial especially when used in combination with other therapies though there are no randomized controlled studies to support its use. Proposed mechanisms of IVIG include the suppression of immunoglobulin synthesis, altered complement binding, and DSA neutralization. Plasmapheresis removes antibodies from circulation, though may stimulate rebound antibody production and should not be used as monotherapy and may offer benefit when used in combination with other therapies. Some studies suggest addition of rituximab [140], whereas others have used bortezomib, eculizumab, or anti-IL-6 antibody added to multimodal therapy [141]. Complement inhibitor therapy has been tried to rescue severe ABMR

[142]. Presently, there is insufficient evidence to support consensus guidelines for the treatment of ABMR. Experts recommend that for patients with allograft dysfunction and risks for ABMR (positive DSA, history of desensitization therapy, and previous transplant) who have biopsy evidence of antibody-mediated injury (C4d+) but minimal pathologic findings (ATN-like changes), treatment should be initiated with high-dose IVIG (2 g/kg) and one dose of rituximab (375 mg/m^2). For those patients with more severe clinical features and pathology, plasma exchange is provided in addition to IVIG and rituximab [139]. Other experimental therapies may be considered but risks versus benefits should be evaluated prior to such considerations [140].

Chronic Rejection or Chronic Allograft Dysfunction

Chronic rejection is included in the broader term chronic allograft dysfunction (CAD) due to recognition that it may not be feasible to differentiate between allograft injury caused by immune and nonimmune causes. Therefore, CAD is a generic term that includes all causes of chronic renal allograft dysfunction associated with fibrosis [143, 144], all causes shown in Table 4. CAD is the most common cause of graft loss in children [143].

The clinical diagnosis is generally suspected when there is gradual deterioration of allograft function (“creeping creatinine”), increasing proteinuria, and worsening hypertension. This is akin to chronic CKD in native kidneys except for presence of additional alloimmune-mediated injury (chronic active T-cell- and antibody-mediated injury). Clinical findings can be insensitive and often underestimate the severity of the underlying pathologic change, and late diagnosis accompanied by progressive pathologic change is expected to lead to graft loss despite therapeutic efforts to intervene.

The pathologic findings of CAD involve all components of renal parenchyma: vasculature, glomeruli, tubules, and interstitium [144]. The glomeruli may be enlarged with a lobular appearance and may include thickened capillary walls with double-contour appearance. Electron microscopy may reveal mesangial cell interposition and endothelial cells swelling and increased thickening and multilayering of glomerular basement membrane. These findings resemble those of membranoproliferative glomerulonephritis, though there are no immune deposits. Immunofluorescence staining may show C4d, which suggests ongoing chronic antibody-mediated injury. Peritubular capillary basement membrane shows splitting and lamination again due to repeated injury and repair. Varying degrees of interstitial fibrosis and tubular atrophy is noted, and focal cellular infiltrate with lymphocytes and plasma cells are often present. Vascular changes include subintimal accumulation of connective tissue and proliferation of myofibroblasts, resulting in thickening of the vessel walls; the presence of vasculopathy has been associated with worse graft outcomes.

The pathogenesis of CAD is complex and involves both immune and nonimmune factors as contributors. Chronic graft injury due to presence of DSA is a major contributor to CAD, and the role of minor HLA antigens and non-HLA antigens in the pathogenesis is less well studied [145, 146]. Chronic CNI toxicity and BKV nephropathy are important contributors to CAD.

Given the limited impact of treatment of CAD, prevention remains an important goal. Individual recipient risks should be considered when planning immunosuppressive regimens with the aim of preventing acute rejections while minimizing CNI nephrotoxicity and BKV nephropathy. Prevention of acute rejection by promoting adherence is an extremely important intervention and requires multidisciplinary approach. Regimens minimizing exposure to CNI from the time of transplantation have not produced favorable results [147], though may be more efficacious with contemporary agents such as belatacept. Converting from CNI to mTOR inhibitors posttransplant appears most effective in patients with relatively preserved renal function (GFR >40 mls/min/1.73 m^2) and limited or absent proteinuria [148]. Furthermore, the use of mycophenolate over azathioprine has been shown to be beneficial in reducing the incidence of CAD at 1 year [149]. With respect to prevention and interventions of nonallogenic risk factors, appropriate donor selection for pediatric recipients should minimize risks associated with poor donor quality. Pediatric preference in allocation favors the allocation of kidneys from high-quality deceased donors to children. With respect to recipient factors, blood pressure should be monitored and treated [150]. Treatment of proteinuria in pediatric renal transplant patients with ACEI or ARB should be considered. These recommendations are based upon studies demonstrating delay of progression of CKD in children and are not specific to pediatric transplant patients [151]. Additional measures include tight control of weight, lipids, and glucose [152]. In conclusion, prevention of both immune- and nonimmune-mediated causes of CAD should be the prime focus to help maintain longevity of the graft since treatment is less than optimal.

Conclusions and Outlook

Transplantation in children carries unique challenges. While issues such as controlling rejection and minimizing side effects are similar between adults and children, maintenance immunosuppressant regimens that affect developmental processes have a disproportionate impact on children. This is particularly true for glucocorticoids, which have many side effects including some that can be quite devastating in pediatric patients. Corticosteroid avoidance has been very successful, when MMF is combined with tacrolimus and either basiliximab or antithymocyte globulin for induction therapy is added; long-term follow-up on these patients with regards to improvements in renal allograft survival and graft function will be very informative, as corticosteroid-free patients also have reduction of comorbidities that drive CAN. With the goal of eliminating steroids, the combination of MMF and tacrolimus may strike the correct balance between adequate and over-immunosuppression. Recently, the use of everolimus has been advocated for minimizing calcineurin inhibitor exposure after renal transplantation, but its use is limited by mTOR-related side effects. There is at present no consensus for immunosuppressive therapy following renal transplantation in children.

Newer drugs such as belatacept have not been systematically studied in the pediatric transplant patient population. Since the approval of belatacept in 2011 for use in de novo adult renal transplantation, this CD80/86–CD28 co-stimulation blocker has been shown to be a valuable treatment option for maintenance immunosuppression [153]. Belatacept in adults has been associated with superior glomerular filtration rate as compared to calcineurin inhibitor–based treatments because of the absence of nephrotoxicity. Additionally, belatacept avoids the cardiovascular side effects (e.g., hypertension and dyslipidemia) caused by a calcineurin inhibitor–based regimen [153]. However, its use is limited to EBV-seropositive patients, since EBV-naive patients on belatacept have an increased risk for PTLD. Nevertheless, there is great interest to bring in belatacept as possible "depot" immunosuppression in the adolescent pediatric recipient, a population that have the highest rates of renal allograft loss and will more likely be plagued with immunosuppression nonadherence and had prior exposure to EBV. Belatacept is safe in adolescents but not yet approved for children or EBV-naive patients given additional risk for developing PTLD [154]. Studies are underway to explore safe protocols for the use of belatacept in adolescent children.

Clearly, much additional work is needed to define optimal immunosuppressive regimens in pediatric renal transplant patients, particularly with respect to newer and evolving regimens. The safety and efficacy of these protocols with special emphasis on long-term renal allograft survival, PTLD, and other malignancies need to be established.

Abstract

Pediatric kidney transplantation is a lifesaving therapy for children with kidney failure. With modern immunosuppression, transplant rejection is as low as 11% in the first year post-transplant. Data from the United States Scientific Registry of Transplant Recipients (SRTR) reported improvements of one-year graft survival for transplants performed in 1987 versus 2010 from 81% to 97%, and 10-year graft survival for transplants performed in 1987 versus 2001 (47% versus 60%) (Pediatrics 133(4): 594–601, 2004). Transplant offers numerous quantifiable and non-quantifiable benefits over dialysis. But some diseases that cause end stage kidney diseases can recur after transplant. The effects of this disease recurrence on patient and kidney allograft health are often devastating. Recurrence of disease accounts for 7–8% of graft losses in pediatric kidney transplant recipients and is the fourth most common cause of graft loss after chronic rejection, acute rejection, and death with a functioning graft (Pediatr Nephrol 24:2097–2108,

Diseases that Affect the Glomerular Microvasculature

Atypical Hemolytic Uremic Syndrome (aHUS)

Hemolytic Uremic Syndrome (HUS) in children is a disease characterized by endothelial swelling. This microvascular inflammation initiates a cascade of platelet aggregation with consequent consumptive circulating thrombocytopenia, turbulent non-lamellar blood flow resulting in hemolytic anemia and renal failure from microvascular occlusion. The inciting event which causes the endothelial injury varies. In children, it is most commonly caused by an enteropathic shiga-toxin producing bacteria such as *E. coli* 0157:H7 (STEC), *shigella dysenteriae*, or *campylobacter jejunii* or rarely organisms such as Streptococcus pneumoniae. This type of HUS is also called typical HUS because is it more common or D+ HUS, referring to the usual occurrence of diarrhea as a preceding event [1, 2]. Progression to end stage kidney disease (ESKD) is less common in this type of HUS and it almost never recurs in the kidney transplant (<1%) [3]. On the contrary, non-shiga-toxin associated HUS has a higher incidence of progression to ESKD (50%) and recurrence after kidney transplantation (80%) [4] and will be the focus of this section.

Atypical HUS (aHUS) is an ultra-rare disease with a reported incidence of approximately 0.5 per million per year. It is caused by dysfunction in the alternate complement pathway which causes uncontrolled complement activity resulting in endothelial injury and swelling with the consequent triggering of the cascade described above. The alternate complement pathway dysfunction is due to mutations in factors of the complement system or antibodies directed against complement factors in 60–70% of patients [5]. On biopsy, classic features of thrombotic microangiopathy (TMA) are observed. Once biochemical, hematological and pathology evaluations have demonstrated TMA, the focus should be on determining the underlying etiology and excluding other diagnoses. The most urgent requirement is to measure ADAMTS13 activity to diagnose or exclude thrombotic thrombocytopenic purpura. Also, infectious evaluation for STEC-HUS should be performed since 5% have no prodromal diarrhea. Serum levels of complement proteins should be measured. Complement functional assays and activation markers can also be obtained. However, delays in obtaining results from genetic or molecular diagnostic studies should not prevent a clinical diagnosis or postpone treatment, as early anti-complement treatment is crucial to preserve renal function and avoid irreversible sequelae. Genes that should be screened include CFH, CD46, CFI, C3, CFB, THBD, CFHR1, CFHR5, and DGKE. The identification of a pathogenic genetic variant in a patient with aHUS reinforces the diagnosis and establishes with accuracy the cause of disease, facilitating patient management, effective treatment, and genetic counseling.

Once ESKD is confirmed, kidney transplantation can be pursued. But caution is merited, and transplantation should be delayed at least 6 months after the start of dialysis, since renal recovery may be observed at varying times after the starting anti-complement therapy. The resolution of hematological TMA features and extra-renal manifestations is a prerequisite for transplantation and special consideration required before pursuing a living donor. Living-related kidney donation carries a risk in the recipient and a risk of de novo disease in the donor, should the donor carry an at-risk genetic variant. Potential donors with evidence of abnormal alternative complement pathway should be excluded.

The risk of aHUS recurrence after transplant varies depending on the mutation identified

Table 1 Risk of aHUS recurrence according to the implicated genetic abnormality

Complement Gene Mutation	Location	Functional Impact	Mutation frequency in aHUS (%)	Recurrence after Transplantation (%)	aHUS & C3GN	Prophylactic eculizumab recommendation
CFH	Plasma	Loss	20–30	75–90	Yes	Yes
CFI	Plasma	Loss	2–12	45–80	Yes	Yes
CFB	Plasma	Gain	1–2	100	Yes	Yes
C3	Plasma	Gain	5–10	40–70	Yes	Yes
MCP	Membrane	Loss	10–15	15–20	Yes	No
THBD	Membrane	Loss	5	1 case	Only aHUS	Yes
CFHR1–5	Circulating	Undetermined	14–23	NA	Yes	Yes

Adapted from Salvadori M, Bertoni E. Complement related kidney diseases: Recurrence after transplantation. World J Transplant. 2016;6:632–645.

aHUS: atypical hemolytic uremic syndrome; C3GN: C3 glomerulopathy; NA: Not available; CFH: complement factor H; CFI: Complement factor I; CFB: complement factor B; C3: Complement component 3; MCP: Membrane cofactor protein; THBD: Thrombomodulin.

(Table 1), occurring most often in patients with gene mutations that encode circulating complement factors (C3, Complement Factor H (CFH), complement factor I) as compared to patients with gene mutations that encode solid phase proteins [6]. TMA could develop at any time in the post transplantation course. TMA manifestations are quite variable and can vary from a limited form confined to the kidney to a full-blown systemic variant. The systemic form of TMA consists of the classic triad of thrombocytopenia, microangiopathic hemolytic anemia, and acute kidney injury. Lactic acid dehydrogenase (LDH) can be elevated with or without a drop in haptoglobin with schistocytes on peripheral blood smear all markers for intravascular hemolysis. Localized TMA presents with non-specific graft dysfunction necessitating the diagnostic allograft biopsy.

Therapies and preventive measures for recurrent aHUS in the allograft include the use of plasma exchange, rituximab (used for aHUS due to anti-factor H antibodies, to help maintain low levels of antibodies), simultaneous liver-kidney transplant (for CFH mutations) [7], and eculizumab. Eculizumab has revolutionized the management of aHUS. Eculizumab is a humanized monoclonal antibody directed against complement protein C5; it inhibits the terminal complement activation by preventing the formation of C5b-9 or membrane attack complex. Prior to the use of eculizumab, patients with recurrent aHUS post-transplant with gene mutations in CFH, CFH-CFHR1–3, CFI, and CFB had 50% risk of progression to ESKD in the first year, which increased to 75% by 3–5 years [8]. Now eculizumab is not only the treatment of choice for aHUS but also for patients with recurrent aHUS. TMA event free status and complete TMA response has been observed in respectively >92 and 50–85% of the aHUS patients who receive eculizumab. Unfortunately, even with eculizumab, graft loss is prevalent in patients with mutations on CFH and CFH/CFHR1 [9]. Plasma exchange does not address the underlying cause of complement dysfunction but can be effective if aHUS is due to anti-FH antibodies, where plasma exchange and adequate immunosuppression effectively reduces the levels of circulating antibodies and inhibits further production [10]. Otherwise, it is only indicated when eculizumab is not immediately available.

Patients with no prior history of aHUS may also present with de novo aHUS after kidney transplantation with classic findings of TMA on pathology and does not represent recurrent disease. Calcineurin inhibitors (CNI) have been implicated by the following mechanisms: loss of the normal balance between the vasodilator peptides (e.g., prostaglandin E2 and prostacyclin) and the vasoconstrictor peptides (e.g., thromboxane A2 and endothelin), results in arteriolar vasoconstriction [11], renal ischemia, and establishment of endothelial injury [12]; CNI-induced platelet activation, pro-coagulant, and anti-fibrinolytic activity have been shown to be involved in TMA evolution, particularly so, with an injured endothelium due to antibody-mediated rejection, ischemia-reperfusion injury, or any other etiology [13]; and microparticle production from endothelial cells, a known effect of Cyclosporine A that can result in activation of the alternate complement pathway, a well-known mechanism that is implicated in TMA evolution [14].

Genetic testing has offered patients with aHUS the advantage of the prophylactic use of eculizumab. Currently, it is recommended in all kidney transplant patients at high-risk of recurrence based on their genetic mutations [15] which includes patients with previous early recurrence and those with previously described pathogenic mutations (Table 1). For those with moderate risk, including patients with no mutations identified, isolated CFI mutations, or insignificant complement gene mutations, the use prophylactic eculizumab is left to the discretion of the clinician. Low-risk mutations, which includes isolated MCP mutations and persistently negative FH autoantibodies, do not need prophylactic eculizumab. Patients who receive prophylactic use before/during transplant have better graft function than those who received eculizumab with aHUS recurrence [16]. Tight blood pressure control and likely lower tacrolimus levels could be recommended in patients with aHUS; since CNIs are now known to cause de Novo TMA as explained above. Duration of eculizumab has been controversial, and so far, it is based on expert opinion. Transplant patients are not good candidates for treatment cessation since discontinuation has been associated with aHUS relapse, particularly in patients with pathologic mutations (vs. those with no identified variants) [17]. Maintenance eculizumab requires infusions every 2 weeks. A new long-acting C5 inhibitor, Ravulizumab (Ultomiris™) has been engineered with increase elimination half-life allowing for extended intervals (from every 2 weeks to every 4–8 weeks infusions). Side effects associated with C5 inhibitors are increased risk of infections from encapsulated bacteria [18]. The risk of meningococcal disease in eculizumab recipients is 1,000 to 2,000 times greater compared to otherwise healthy individuals in the United States. Patients should receive meningococcal vaccination, including type B, ideally 2 weeks prior to initiation of eculizumab therapy. Since it is unknown whether anti-meningococcal antibodies are protective in the setting of complement blockade, it is recommended to remain on Penicillin while on C5 inhibitor and up to 2–3 months after discontinuation. However, vaccination should not delay the start of eculizumab. The following agents are under investigation: The anti-C3b blocker, compstatin analog Cp40, and anti-C3 convertase monoclonal antibodies.

Glomerular Diseases with Potential to Recur

FSGS

Focal segmental glomerulosclerosis (FSGS) is the most common cause of steroid resistant nephrotic syndrome leading to end-stage kidney disease (ESKD). Data from the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) show that FSGS carries the highest likelihood of progressing to ESKD, exceeding the risk of hypoplasia, obstructive uropathy, and reflux nephropathy. According to NAPRTCS, nearly 60% of such children with a diagnosis of FSGS progress to dialysis or transplantation within 24 months of entry into the registry [19]. Incidence of nephrotic syndrome in children is about 20 cases per million [20]. It is estimated that 20% of these cases are FSGS. In adults, the estimated incidence of FSGS is 7 per million [21]. An estimation of the incidence and prevalence of FSGS in children is hampered by the fact that most children with nephrotic syndrome, unlike the majority of adults, are not routinely subjected to renal biopsy. Therefore, prevalence and incidence figures are extrapolated from clinical reports, registries, and renal biopsy materials [22]. In addition, FSGS is a pathologic finding that can be caused by diseases that are immunologic, genetic, or other. Therefore, the reported frequency varies significantly in the literature, since many different entities culminate in a similar biopsy phenotype on biopsy [23]. FSGS can be classified as primary and secondary. Primary (idiopathic) FSGS has been attributed to an elusive circulating factor. Secondary FSGS occurs due to viruses (human immunodeficiency virus type 1, parvovirus and other less characterized such as simian virus 40, cytomegalovirus and Epstein-Barr virus), drugs (heroin, bisphosphonates, interferon therapy, mammalian target of rapamycin), and secondary to hemodynamic adaptations (due to reduction number of functioning nephron units) or hemodynamic stress (due to morbid obesity, cyanotic heart disease, sickle cell anemia). In the case of secondary FSGS, the treatment usually requires management of the underlying cause. If transplant is necessary in these patients, recurrence is rare if underlying disease/cause is treated. The familial (genetic) forms result from abnormalities in gene transcription controlling assembly of the slit diaphragm, cytoskeleton, and adhesion complexes, all of which are essential for podocyte function, in maintaining a filtration barrier. A transplant therefore is curative without risk of recurrence in genetic FSGS. This section will mainly cover the entity of primary FSGS (Fig. 1; Table 2).

Based on current data, FSGS has poorer transplant outcomes than most other causes of ESKD [24], largely because of disease recurrence in the transplanted kidney, affecting 15–36% of pediatric transplants [25–27]. The etiology of recurrence is unknown. Given the recurrence rate after kidney transplant, the presence of a circulating permeability factor has been studied [28]. There have been published reports of patients with FSGS who developed immediate recurrence of nephrotic syndrome. In some cases, the graft was removed and re-transplanted in a patient with a different cause of ESKD with excellent outcomes. This provides strong evidence of the presence of a circulating factor as the pathogenic mechanism for the recurrence of FSGS posttransplant [29, 30]. A serum soluble urokinase receptor (suPAR) has been proposed as the factor leading to foot process effacement and proteinuria. Nevertheless, the diagnostic test accuracy of suPAR remains suboptimal in predicting FSGS recurrence, [31] and this has been countered by others.

Unfortunately, we are unable to predict recurrence, but there are identifiable risk factors including an early onset of nephrotic syndrome; presentation as a child and rapid progression to ESKD. Data demonstrate that 50% of those whose progression from diagnosis to ESKD occurs in

less than 3 years will recur after kidney transplantation. Other risk factors include initial treatment resistance, initial steroid sensitivity with progression to steroid resistance, non-black race, and recurrence in previous transplants. The recurrence rate in a subsequent graft approaches 80% [32]. Notably, clinically significant disease recurrence does not necessarily affect all re-transplants following loss of the first graft to disease recurrence. Importantly, selected patients who experience first graft failure due to recurrent glomerular disease should not be precluded from receiving a second transplant [33]. Factors reported not to affect recurrence include HLA mismatch, histologic subtype, chronic dialysis duration, and type of immunosuppression.

Individuals with known genetic causes of FSGS do not appear to be at risk for recurrence in the transplanted graft. It is currently prudent to perform genetic testing as the presence of a genetic etiology portends a reduced recurrence risk, and if present could advocate for living donation with excellent outcomes [34]. Otherwise, in patients with primary FSGS, there is no evidence of the superior graft survival advantage seen in non-FSGS transplants in living-related donor over the deceased donor transplants [35]. Currently, deceased donor transplants are preferential in individuals with primary FSGS.

Recurrence can occur immediately after transplantation and result in massive proteinuria, hypoalbuminemia, acute tubular necrosis, and graft failure due to small vessel thrombosis. It remains the most common cause of graft loss in pediatric renal transplantation. Early on, foot process effacement is the only finding on biopsy, characteristic FSGS lesions may follow later in the course [36].

Management remains controversial. The current approach is often based on anecdotal evidence, derived from non-blinded, non-randomized, small case series. Recognizing the role of circulating factors in the pathogenesis, plasmapheresis is used prophylactically prior to transplantation or immediately after when there is evidence of recurrence disease. A recent study has shown that prophylactic plasmapheresis did not provide any additional benefit prior to the transplant in living and deceased donors did as regards the incidence (27% vs 26%, $P = 1.0$) or time to recurrence of FSGS in the kidney allograft ($P = 0.22$) [37]. This has been supported by others [38].

Prompt treatment of recurrence with these therapies may result in improved outcomes with or without rituximab [39].

Twenty to sixty percent remission rates have been reported in different centers at variable lengths of post-transplant plasmapheresis treatment [37]. Immunosuppression protocols using rituximab and calcineurin inhibitors have also suggested a beneficial effect, although these findings are quite variable. Rituximab appears to have non-B-cell related effects as it sustains the integrity of the podocyte actin cytoskeleton and prevents apoptosis [40]. Rituximab can be recommended as a treatment for cases that have failed either the initial plasmapheresis or weaning from plasmapheresis although its benefit has not been shown consistently [41]. Abatacept is a co-stimulatory inhibitor that targets B7–1. Patients with FSGS have been found to be positive for B7–1 immunostaining of podocytes in kidney-biopsy. Abatacept induced partial or complete remissions of proteinuria in some possibly by stabilizing the β1-integrin activation in podocytes and reducing proteinuria in patients with B7-1-positive glomerular disease [42]. However, this was not replicated by others [43] and this drug has not gained popularity as an effective treatment. LDL-apheresis in combination with steroids has also been shown to be a promising treatment of FSGS recurrence post-transplant [44] and is gaining traction in the nephrology community.

C3 Glomerulopathy (45%)

C3 glomerulopathy encompasses C3 glomerulonephritis (C3GN, previously membranoproliferative glomerulonephritis type III) and dense deposit disease (DDD, previously MPGN II). This set of diagnoses is characterized by the glomerular deposition of C3 in the absence of Ig deposition [45]. C3GN is an ultra-rare disease, only reported to be the primary diagnosis leading to ESKD in 0.8% of children (NAPRTCS). DDD is very rarely the cause of ESKD in children [19]. Histologic differences based on electron microscopy are as follows: DDD is characterized by dense osmiophilic intramembranous deposits and C3GN by light dense amorphous mesangial, paramesangial, subendothelial, and subepithelial deposits.

The predominance of C3 deposition within the glomerulus suggests the presence of dysregulated alternate complement cascade. Most frequently, dysregulation occurs at the level of C3 convertase of the alternative pathway in the fluid phase and is driven by genetic and/or acquired defects. Our understanding of the genetics of C3G is not yet comparable to that of aHUS. More data is required to inform genotype-genotype correlations.

Genetic mutations (Factor H, Factor I) or autoantibodies (e.g., C4 nephritic factor directed against C3 convertase or Factor H autoantibodies) resulting in dysfunctional complement regulatory proteins and therefore uncontrolled amplification of the C3 protein have been implicated [46] (Table 1). As in aHUS, all planned recipients of a living-related kidney should be screened for genetic abnormalities, and if one is present, the donor should be tested to exclude that genetic abnormality. The theoretical risk that donation may trigger disease onset must be discussed with the donor.

In contrast to the acute presentation of aHUS, with C3GN the disease follows a chronic indolent course. Acquired partial lipodystrophy and retinal drusen are reported and appear to be direct consequences of complement activation.

Recurrent disease (45%) is the major contributor to poor graft survival, with over 50% of patients with disease recurrence reported to experience allograft failure [47]. The timing and clinical presentations of patients with C3GN and DDD are different, with DDD more likely to recur later post-transplant and often associated with no clinical manifestations other than allograft dysfunction. C3GN presents with proteinuria, hematuria, hypertension, and declining glomerular filtration rate. Hypocomplementemia is commonly observed. Younger age at presentation and crescents on original biopsy have been associated with increased recurrence risk. Transplant glomerulopathy may be difficult to distinguish from recurrent C3GN since histological features may be very similar.

A specific treatment approach is not well established. All patients should target optimal blood pressure control below the 90th percentile or less than 120/80 mmHg. Priority agents include angiotensin receptor inhibitors (ACE) and angiotensin receptor blockers (ARB). Lipid control is also recommended. Data is insufficient to recommend eculizumab as a first-line agent, though it is starting to be used if there are identified mutations [48] (see Table 1). Studies have included small numbers and heterogeneous patients. Hopefully, with the new classification, it will lead to more personalized treatment strategies for those who develop recurrent C3 glomerulopathy post-transplant.

Membranous Nephropathy

Membranous nephropathy is the most common cause of nephrotic syndrome in older adults but is an uncommon condition in children. The disease is characterized by the presence of subepithelial immune deposits with expansion of the glomerular basement membrane, causing podocyte injury.

Recurrent membranous nephropathy ranges between 10% and 45%. The reason for the wide variability is that the diagnosis is made only by biopsy. The discovery of autoantibody against the podocyte phospholipase A2 receptor (PLA2R) led to better understanding, management, and treatment of patients with idiopathic membranous nephropathy [49].

Risk factors for disease recurrence include: high titer of anti-PLA2R antibody, rapid progression of native ESKD, and prior allograft failure secondary to recurrent membranous nephropathy (especially if it occurred less than 5 years post-transplant).

Recurrent membranous nephropathy is typically observed 13–15 months after transplantation, although may also be observed within weeks. Patients can present with proteinuria and allograft dysfunction or subclinical histological recurrence. Higher relative risk of allograft failure has been reported after disease recurrence.

Treatment typically includes a combination of anti-proteinuric agents, corticosteroids, rituximab, calcineurin inhibitors, and alkylating agents. Patients with no or minimal proteinuria, stable glomerular filtration rate and only histological evidence of recurrence can be treated with non-immunosuppressive therapy alone as ACE or intensive blood pressure control. With significant proteinuria, both non-immunosuppressive and immunosuppressive therapy should be used. With rituximab, 80% achieve complete or partial remission when used for early disease recurrence post-transplant [50]. Bortezomib has been prescribed for rituximab resistant cases [51].

MPGN Type 1

Membranoproliferative glomerulonephritis type I is the primary diagnosis in about 2% of pediatric kidney transplants [19]. The pathogenesis involves a dysregulation of the classical or lectin complement system, caused by increased amounts of circulating immune complexes due to chronic antigenemia (chronic infections, autoimmune diseases, malignancies, plasma cell dyscrasias, or other persistent antigen stimuli) leading to the activation of the classical or lectin pathway of complement. Therefore, they present with a concurrent low level of C3 and C4. Histologically, it is characterized by glomerular immunoglobulin deposition in the subendothelial glomerular space, giving rise to marked mesangial proliferation [52]. Clinically patients present with nephrotic, nephritic, or nephritic-nephrotic overlap syndromes.

Rate of recurrence is about 30% in adults and pediatrics, although it appears to be higher in pediatric patients than that of adult patients.

Recurrence is manifested by proteinuria. Despite the risk of recurrence, graft survival is comparable to that of patients with other causes of graft failure [53].

Treatment includes plasmapheresis, steroids, and other immunosuppressive agents. However, the optimal treatment strategy remains undetermined.

IgA Nephropathy

IgA nephropathy is an immune complex-mediated glomerulonephritis. It has been recognized worldwide, although prevalence varies from one country to another. Its clinical presentation is frequently associated with an upper respiratory tract or gastrointestinal infection and onset of gross hematuria. On biopsy, granular electron-dense deposits are observed in the glomerular mesangial area by electron microscopy and confirmed as containing IgA and C3 by immunofluorescence. The immunopathologic features are very similar to Henoch-Schonlein purpura nephritis.

Recurrent IgA nephropathy is common. Its presentation is often relatively benign and tends to occur late post-transplant. The majority of patients have a relatively benign presentation with microscopic hematuria or evidence of IgA deposition in allograft biopsies. Proteinuria or progressive graft dysfunction can also be seen. Graft lost is still reported after IgA recurrence but with better outcomes than other recurrent conditions. Markers for progression, as with all glomerulonephritis, are increased urinary protein excretion and increased sclerosis or fibrosis on biopsy.

Several risk factors for disease recurrence have been described including younger age, recipients of zero-HLA mismatched live-related donor kidneys (though other data suggests no association with full HLA match and risk of recurrence [54]), steroid-avoidance or early steroid-withdrawal immunosuppressive regimens, the non-use of induction therapy, HLA allelic subtypes, increased serum IgA concentration, crescentic (rapidly progressive) IgA nephropathy in the native kidneys [55]. Pre-transplant tonsillectomy does not appear to affect IgA nephropathy recurrence [56].

The optimal treatment of recurrent IgA nephropathy remains unknown. Maintaining or changing to a calcineurin-inhibitor and corticosteroids-based immunosuppressive regimen in addition to anti-proteinuric treatments is the current practice. ACE or ARB therapy may delay progression from recurrent disease in the allograft [57, 58].

A different scenario is when there is incidental finding of IgA from donor source. This has been mostly reported in the Japanese and Chinese literature. Presence of IgA on the graft biopsy has not been shown to have an adverse association with graft or patient survival [59].

Other Glomerulonephritis (GN)

Systemic Lupus Erythematosus (SLE). SLE is an episodic, multisystemic, autoimmune disease with polyclonal B cell activation, and widespread production of autoantibodies. There is widespread inflammation of blood vessels and connective tissue due to immune complex deposition. It is more common in females and in the black population. Renal disease is more severe in patients with childhood-onset lupus than those with adult-onset disease. The reported recurrent lupus nephritis varies between 0–40%, and those who experience recurrence have greater risk of allograft failure and mortality [60].

Anti-glomerular Basement Membrane (GBM) GN and Goodpasture's Syndrome Goodpasture is a “pulmonary-renal-syndrome” characterized by pulmonary hemorrhage and crescentic nephritis. It is an auto-immune complex mediated disease. The presence of anti-GBM antibodies in peripheral blood confirms the diagnosis. The incidence of recurrent linear immunoglobulin G (IgG) staining in the transplant may be as high as 50%. However, most patients remain asymptomatic. Allograft failure from disease recurrence is exceedingly rare in the modern era of immunosuppression [61].

Anti-neutrophilic Autoantibodies (ANCA) Vasculitides. ANCA associated vasculitides are a heterogeneous group of rare autoimmune conditions that causes an inflammation of blood vessels with various manifestations. It includes three main diseases which are granulomatosis with polyangiitis (GPA), eosinophilic granulomatosis with polyangiitis (EGPA; previously known as Churg-Strauss syndrome), and microscopic polyangiitis (MPA). In patients with ANCA-associated vasculitis, the relapse rate (often extra-renal) has been reported at 0.02 per patient-years, with no consistency with disease severity prior to transplantation and recurrence post-transplantation [62].

Non-glomerular Causes

Primary Oxalurias

Primary hyperoxaluria type 1 (PH1) is an autosomal recessive disorder due to decreased activity of hepatic alanine-glyoxylate aminotransferase. This leads to over production of oxalate by the liver, increased urinary excretion of oxalate and glycollate and progressive kidney failure. Reduced clearance leads to deposition of oxalate in body tissue. Confirmation of diagnosis is by genetic analysis or enzyme assay on liver biopsy. Infantile type is severe, presenting with nephrocalcinosis and early ESKD. Crystals can be seen in the retina and bone marrow. The only treatment is removing the source of excess oxalate production via a liver transplant as early as possible. Up to 40% patients are pyridoxine sensitive. Other adjuvant treatments include large fluid intake and oral citrate. Hemodialysis provides better clearance than peritoneal dialysis.

In patients with primary hyperoxaluria, recurrence of oxalate deposits in the graft occurs universally and can lead to graft failure in the same way it led originally to ESKD. Combined or sequential liver-kidney transplant is the best approach to preventing systemic oxalosis. Transplantation of liver first, with intense dialysis before kidney transplantation could potentially lower the burden of oxalate in the body and decrease the likelihood of compromising the graft [63].

Summary

Disease recurrence is currently one of the most challenging issues in pediatric kidney transplantation. There have been significant advances in the understanding of the epidemiology, pathogenesis, and classification of recurrent diseases. Despite these advances, considerable uncertainty remains in the approach and treatment. Better understanding of disease pathophysiology, risk evaluation and individualized treatment strategies will improve morbidity and patients' outcomes. Genetic testing should be performed whenever available. It is imperative to establish global registries collecting comprehensive in-depth data of pediatric patients with recurrent disease, bio-repositories, as well as novel trials designed to test the efficacy of specific treatment strategies in multicenter randomized controlled trials to address the knowledge deficiency in this disease. Disease recurrence should not preclude future pediatric transplantation, it should rather urge to investigate further and establish personalized specific treatment strategies.

Abstract

Infections are a major cause of morbidity and mortality after transplantation, not only in the immediate post-operative period but also beyond. The infectious burden in the post-transplant setting is mostly related to the iatrogenic immunosuppression required to avoid graft rejection, but also to other factors such as surgical site infection, cytopenias, and community exposures (Fishman, Am J Transplant

17:856–79, 2017). In comparison to adults, pediatric kidney transplant recipients are at further risk for infections because they have not had the opportunity to encounter many pathogens and mount an immune response prior to transplant. This chapter focuses on frequently encountered bacterial, viral, fungal, and parasitic infections following pediatric kidney transplantation.

Keywords

Kidney transplantation · Donor-derived infection · Herpesviruses · BK virus · Urinary tract infection

Introduction

In the previous chapters the reader has become acquainted with the science of pediatric kidney transplantation. The reader will also have noted the tremendous successes achieved in this field over the past few decades, with marked improvement in patient and graft survival over the last decades [2–4]. Due to improved diagnostic techniques, clinicians' awareness, longer survival, and more potent immunosuppressive regimens, infectious complications such as post-transplant lymphoproliferative disorder (PTLD) and BK virus allograft nephropathy (BKVAN) are becoming more prominent and more frequent [5–7]. The infection-hospitalization cumulative incidence is much higher at 47% in children in the first 3 years post-kidney transplant than while on dialysis or in comparison to adults post-kidney transplant [8]. Unlike adults, the total cumulative infection incidence in children did not drop in recent years [9]. In this chapter we will discuss the various infectious complications associated with pediatric kidney transplantation (Table 1).

Special Considerations in Pediatric Transplantation

When compared to healthy individuals, organ transplant recipients of any age are at greater risk for infections since the currently used immunosuppressive agents also suppress the defense mechanisms against infections [10]. Besides the immunosuppressive agents, other factors contribute to the net state of immunosuppression, such as cytopenia, loss of integrity of the mucocutaneous barrier, underlying immunodeficiency, and post-operative complications [1]. In addition, *pediatric* recipients of organ transplants have some unique (usually additional) features that add to their risk for complications. By virtue of their younger age, these recipients are potentially exposed to disease complications and medication toxicities for a longer period of time. The risk for some infections, especially viral infections, is higher if the child has not been exposed to that organism while still immunocompetent. Thus, a primary infection in a host who is immunosuppressed tends to be more severe. The kidney allograft often acts as the source for the primary infection, since most children receive an adult donor kidney, which harbors latent viruses – especially herpesviruses and polyomaviruses – to which the donor has previously been exposed. Many children may not have had the opportunity to receive all vaccinations prior to transplant, thereby preventing development of immunity against vaccine-preventable diseases.

Table 1 Typical post-transplant infectious complications

Infectious
Bacterial
Wound infections: usually *Staphylococcus/ Streptococcus* spp
Central line infections
Pneumonia
Urinary tract infections: usually Gram-negative rods
Mycobacterium tuberculosis
Bartonella henselae

Bacterial Infections

Urinary Tract Infection

Urinary tract infections (UTI) affect kidney transplant recipients more than any other type of transplant recipients [11]. UTIs are the most common bacterial infection in kidney transplant recipients, both in adults [12, 13] and children >5 years [14]. The percent of renal transplant recipients who will experience a UTI ranges from 20% to 65% in the first year post-transplant [12, 15] and 40–80% by 3 years post-transplant (Table 2) [16–20]. The highest incidence of UTI happens 3–6 months following kidney transplantation [11]. UTI is not only a cause for morbidity but is also associated with higher rates of graft loss and patient death [16, 21]. Early UTI (within 6 months of transplant) elevated the risk for graft loss in children, while late UTI did not [22]. The urogenital tract is the most common entry point for the development of sepsis [23], and UTI are responsible for 30% of sepsis episodes following kidney transplantation [11]. Risk factors for UTI in children include bladder abnormalities, the need for chronic or prolonged bladder catheterizations, and placement of a ureteral stent [17, 24]. In adults, diabetes mellitus and cardiovascular disease are comorbid factors that also associate with a higher incidence [16].

Table 2 Complication rates in multicenter randomized trials in pediatric kidney transplantation

Complication		Infections/malignancies		
		UTI	CMV	PTLD
Trompeter et al. (CsA vs Tac) [137]	Control arm	33%		2%
	Study arm	29%		2%
Grenda et al. (basiliximab addition) [138]	Control arm	28%	2%	2%
	Study arm	19%	7%	0%
Offner (Basiliximab vs placebo) [139]	Control arm	23%	9%	5%
	Study arm	35%	13%	2%
SNS01 study (steroid avoidance) [140]	Control arm	31%	9%	0%
	Study arm	25%	14%	0%
TWIST study (early steroid withdrawal) [141]	Control arm	13%	12%	0%
	Study arm	17%	12%	2%
Tonshoff et al. (everolimus versus MMF) [142]	Control arm	24%	6%	0%
	Study arm	25%	2%	2%

Footnote: The IVIST trial [143] compared the steering of immunosuppression based on virus-specific T-cell levels in the intervention arm to trough level immunosuppressive drug monitoring. Reduced levels or daily immunosuppressive doses in the intervention arm were associated with a trend to reduced EB viral replication and no adverse impact on allograft function or CMV replication

UTIs in kidney transplant recipients are usually classified as asymptomatic bacteriuria, acute simple cystitis (no systemic symptoms), and complicated UTI/pyelonephritis (systemic symptoms or indwelling stents, catheters or nephrostomy tubes) [11]. Recurrent UTI is defined as ≥3 episodes in 12 months [11].

The organisms implicated are usually the same as in immunocompetent individuals, mainly Enterobacteriaceaes such as *Escherichia coli*, followed by *Klebsiella* spp and *Proteus* spp. A higher percentage of UTIs in transplant patients are due to unusual organisms such as *Pseudomonas* spp and *S. saprophyticus* [11, 25]. Clinical symptoms include fever, dysuria, graft tenderness, and cloudy urine. In some patients, systemic symptoms such as fever may be masked by the immunosuppressive medications. A rise in serum creatinine often occurs and can mimic acute rejection. UTIs can also precipitate an acute rejection. The diagnosis of UTI is usually confirmed by urine culture, though patients on trimethoprim-sulfa prophylaxis for *Pneumocystis jirovecii* may not demonstrate positive cultures. In that case, radionuclide scanning or clinical judgment may be necessary. Recently, the emergence of multidrug-resistant organisms as a cause of UTI following kidney transplantation may be associated with poorer prognosis and an increased likelihood of recurrent UTIs [11]. Treatment is with antimicrobial agents. Empirically, betalactams or quinolones with coverage against common Gram-negative organisms should be used as a first -line therapy [11]. Once the organism is identified, the most specific and cost-effective antimicrobial can be prescribed. Treatment route and total duration vary somewhat according to the severity of the infection, recipient age, and other risk factors. Shorter oral 5–7 days courses such as used in immunocompetent people can be used for milder cystitis episodes in older children. In more severe acute pyelonephritis in a younger child who was recently transplanted, intravenous antimicrobial therapy for 14–21 days is preferred. Currently, the available evidence does not support routine treatment of asymptomatic bacteriuria [11].

Not all centers prescribe routine prophylaxis for UTI. Trimethoprim-sulfa, if given daily, may serve as both UTI and *Pneumocystis jirovecii* prophylaxis and is recommended in the KDIGO and AST guidelines [11, 26].

Other Bacterial Infections

Other bacterial infections, such as wound infections, line sepsis, and pneumonia, are seen with significant frequency in kidney transplant recipients. Wound infections and line sepsis are commonly due to Gram-positive *Staphylococcus* spp and *Streptococcus* spp. While many (44%) cases of pneumonia are bacterial in origin, pneumonia can also be due to viral or fungal organisms [27]. In adult transplant recipients, cellulitis and bacterial abscesses are frequent problems, largely due to co-morbid diabetes mellitus. The detection and treatment of these infections is generally no different than standard investigation and treatment in immunocompetent hosts, though duration of therapy may be longer.

Bartonella henselae infection (also known as cat-scratch disease) has been reported in pediatric organ transplant recipients, including kidney transplants [28]. This infection typically presents as fever and lymphadenopathy, thus becoming a differential diagnosis for PTLD. However, unlike PTLD, this infection is curable with antimicrobial therapy.

In developing countries, *Mycobacterium tuberculosis* infection occurs more commonly. The incidence is <2% in Western countries but ranges from 5% to 15% in Asian and African countries [29, 30]. Use of cyclosporine, co-existing diabetes mellitus, and chronic liver disease increase the risk for post-transplant tuberculosis [31]. Active tuberculosis infection can present with multiple symptoms, including weight loss, cough, fever and lymphadenopathy, again acting as a differential diagnosis for PTLD. However, pulmonary involvement is more common than lymphadenopathy in the post-transplant setting. Early diagnosis is best achieved by staining for acid-fast bacilli or DNA amplification by polymerase chain reaction (PCR) from sputum, bronchoalveolar lavage or gastric aspirates. A four-drug regimen, similar to the regimen recommended in the general population, should be used in case of active tuberculosis after transplantation [32]. Rifampicin can be part of the regimen but careful attention should be paid given its interaction with tacrolimus/cyclosporine/steroids, requiring to markedly increase the dose of immunosuppression. Alternatively, rifabutin could be used instead of rifampicin given its milder interactions [32].

Latent tuberculosis is defined by the evidence of exposure to the bacilli (either by a tuberculosis skin test [TST] or an interferon-gamma-release assay [IGRA]) in the absence of symptoms or radiologic abnormalities. When diagnosed after treatment, treatment with isoniazid for 9 months should be considered [32].

Viral Infections

Cytomegalovirus

Cytomegalovirus (CMV), now also called humanherpes virus (HHV)-5, is a double-stranded DNA virus of the herpesvirus family. In pediatric kidney transplantation, the incidence of CMV infection has been highly variable, ranging from 6% to 40% (Table 2) [33–36]. The variation is partly due to differing definitions (e.g., asymptomatic replication versus CMV syndrome versus CMV organ disease) and partly due to different detection methods [35, 37]. A retrospective study in pediatric transplant recipients using pp65 antigenemia reported a viremia rate of 21% and disease rate (viremia plus organ involvement) of

9.7% [35]. In pediatric kidney transplant recipients, incidence of CMV infection and disease were 40% and 15%, respectively [38]. CMV is especially important because of its dual effects: it causes significant morbidity by direct infection, yet its immunomodulatory effects can predispose to other infectious complications [39]. CMV infection post-transplant can be as a primary infection, a reactivation infection, or a superinfection. Of these, primary infection in the immunocompromised host is the most likely to lead to disease and often occurs when a seronegative pediatric recipient receives a seropositive kidney transplant [35, 36]. Both CMV viremia and disease usually occur within the first few months post-transplant, though routine antiviral prophylaxis has led to a shift, with more frequent late-onset CMV disease appearing after prophylaxis ends [37]. CMV infection may present as asymptomatic replication, CMV syndrome, characterized by fever, myalgias, malaise, leukopenia and thrombocytopenia, or CMV organ disease, in which there is clinical evidence of organ involvement such as pneumonitis or colitis [39, 40]. The transplanted kidney is at higher risk for CMV infection than the native organs are, but pulmonary, liver, and gastrointestinal tract involvement are common, regardless of the organ transplanted.

As stated above, in addition to causing direct infection, CMV has significant indirect effects including an increase in the overall state of immunosuppression leading to a greater risk for heterologous infections [41]. CMV infection also increases the risk of EBV-associated PTLD [42]. In addition, CMV and acute rejection are interrelated. Kranz et al. showed that a previous CMV infection is a risk factor for acute rejection, while rejection is known to release of tumor necrosis factor, triggering the process that ultimately leads to CMV replication [35].

Prevention of CMV infection can be accomplished with either (1) universal prophylaxis: the administration of anti-CMV therapy to all patients; (2) preemptive treatment: the systematic monitoring of CMV replication with administration of anti-CMV therapy if viral load reaches a certain threshold; or (3) a hybrid approach combining a short prophylaxis following by monitoring of CMV replication [39, 40]. There is some controversy as to the optimal strategy, as both methods have advantages and disadvantages. In one study of pediatric liver transplant recipients, preemptive therapy was superior to prophylaxis [43]. Most guidelines recommend universal prophylaxis for high risk patients (e.g., seronegative recipients of seropositive organ), with preemptive therapy reserved for patients at low or intermediate risk [39, 40]. Although several agents are available for prophylaxis, ganciclovir and valganciclovir have largely supplanted either oral aciclovir or CMV immune globulin (CMVIG) as the recommended regimen for CMV prevention. Oral ganciclovir has a poor bioavailability and must be taken in large doses three times daily. Valganciclovir has a superior bioavailability, with a pharmacokinetic profile similar to intravenous ganciclovir. The standard duration of prophylactic therapy is now 180 days in adults. Although evaluated in phase III trials, no CMV vaccine is currently available.

Detection of CMV DNA or RNA by polymerase chain reaction (PCR) has now supplanted the pp65 antigenemia assay. Serum and whole blood DNA correlate well in case of CMV [44] and now an international CMV standard is more widely used.

When CMV disease does occur, treatment with oral valganciclovir or intravenous ganciclovir is equally effective [45]. Oral valganciclovir is usually preferred over intravenous ganciclovir, unless in case of life-threatening infection [39, 40]. The optimal duration of treatment has not yet been defined, and current protocols recommend continuing treatment until the viral load becomes undetectable for at least two consecutive measures. Cidofovir and foscarnet are second-line agents to be considered in case of (suspicion of) resistance to (val)ganciclovir [39, 40]. Novel agents such as letermovir have not been well studied in the SOT setting and resistance may develop earlier than with other anti-CMV agents [46].

Epstein-Barr Virus and PTLD

Epstein-Barr virus (EBV; now also known as HHV-4) is another DNA herpesvirus that causes significant morbidity post-transplantation. Like the other herpesvirus CMV, this virus commonly infects immunocompetent people sometime in childhood and establishes a prolonged latency in reticuloendothelial cells. Thus, the patterns of infection are identical to CMV: primary infection (often from the graft of a seropositive donor), reactivation, or superinfection. Again, like CMV, the primary infection in an immunosuppressed transplant recipient is more virulent. Unlike CMV, EBV infection does not seem to have many indirect effects except for the development of PTLD, which is an uncontrolled proliferation of immune cells (typically B cells) in the absence of T-cell control because of post-transplant immunosuppression [7].

EBV infection can be asymptomatic or present as a nonspecific viral syndrome, similar to CMV infection [47]. Routine PCR monitoring suggests that the rate of EBV infection in EBV seronegative pediatric transplant recipients (as defined by systemic viremia) ranges from 50% to 80% [48–50].

EBV viremia, in contrast to PTLD, can be asymptomatic or associated with mild nonspecific viral symptoms. In the past, the diagnosis was made by documenting seroconversion (EBV IgM positive or significant rise in IgG titer). Unlike with CMV, in the case of EBV, testing can be performed against EB nuclear antigen or viral capsid. The former turns positive early, after recent infection and the latter in more distant infection. Currently, PCR amplification of viral DNA has supplanted serological assays for the diagnosis of active EBV infection [51]. The reader should note that PCR techniques for EBV DNA amplification vary greatly based on the type of sample and laboratory standards. Thus, PCR values from peripheral blood leucocytes and whole blood generally correlate with each other but not with PCR values from plasma [52, 53]. An international standard for EBV was introduced in 2013 but did not eliminate the variability in results from different laboratories [54]. The KDIGO guidelines recommend the following post-transplant EBV schedule for high-risk D+/R patients: once in the first week after transplant, at least monthly for the first 3–6 months, then at least every 3 months until the end of the first year with re-initiation of monitoring after treatment for acute rejection [55].

In pediatric cases especially, most PTLDs are due to EBV [47]. This condition is not a true malignancy since the immune system can regain control of B-cell proliferation if extrinsic immunosuppression is reduced and EBV-directed CD8+ T cells regain function.

PTLD incidence in pediatric kidney transplantation was previously low at <1%, but then climbed to more than 4% before a more recent drop (Table 2) [2, 56–59]. The main risk factors for PTLD after pediatric kidney transplantation is a D+/R-serostatus, even though the use of antilymphocyte globulin and young recipient age are also considered as risk factors [47]. PTLD can present clinically in many ways [59, 60]. Most often the patient has lymphadenopathy, fever, or symptoms related to pressure on internal organs from an internal lymphoid mass. Definitive diagnosis requires histological confirmation, though imaging can help with appropriate tissue acquisition and staging. PTLD are categorized in different forms or early lesions, polymorphic lesions, monomorphic lesions, or Hodgkin-like lymphomas according the 2016 WHO classification [61]. Monomorphic PTLD is generally more severe than polymorphic.

Due to an absence of evidence of benefit, antivirals, IVIG, and rituximab are not routinely recommended for the prevention of EBV disease [47]. EBV vaccines have not been successful enough so far for clinical implementation.

There is no universally accepted treatment for EBV infection post-transplant [47]. Reduction in immunosuppression is one modality. The antiviral agents ganciclovir and valganciclovir have activity against EBV even though their clinical benefit is still debated. Aciclovir is not effective against EBV. The duration and route of antiviral treatment is not standardized but some centers will treat until the EBV PCR has turned negative. Whether all patients with acute EBV seroconversion need reduction in immunosuppression or antiviral treatment is a burning question in pediatric transplantation [47, 62, 63]. Children in particular can develop a chronic high load carrier state without ever progressing to PTLD [64]. Nevertheless, high EBV DNAemia has a good negative predictive value but a poor positive predictive value for the diagnosis of PTLD [47, 65–67].

Treatment of PTLD usually involves a sequential process [68, 69]. Reduction of immunosuppression reduction is typically the first intervention. Antivirals and/or IVIG are not recommended in the absence of other intervention [47]. If reduction of immunosuppression is not sufficient, the anti-CD20 antibody rituximab should be used in CD20 + B-cell PTLD. Chemotherapy is usually reserved for higher grade cases, such as progressive CD20+ PTLD despite rituximab or CD20- PTLD [47]. Rituximab can be added to either full dose or attenuated dose chemotherapy with good results with either type of combination therapy [70, 71]. Surgery and radiotherapy can be considered in selected cases. EBV-specific T-cell infusions are being investigated as a treatment for EBV + PTLD.

Varicella Zoster-Virus

Varicella-zoster virus (VZV), now also known as HHV-3, is the most infectious of the human herpesviruses. Primary infection with VZV results in chickenpox. Following primary infection, the virus remains in the body in a latent state from which it may be reactivated, resulting in cutaneous herpes zoster, or shingles. Incidence of any type of VZV infection in adult kidney transplant recipients was 7.4% in one study [72]. Children are more likely to be VZV seronegative at the time of transplantation and primary infection is a significant cause of morbidity and mortality [73, 74]. Routine VZV vaccination has been documented to reduce the incidence of primary VZV infection post-transplantation [75]. It is recommended that all transplant candidates over 9–12 months of age receive immunization with the VZV vaccine [76]. Studies in children with chronic kidney disease and on dialysis suggest that two doses, rather than one, may be necessary to elicit protective antibody levels. Therefore, antibody levels be obtained at least 4 weeks following immunization, and a second dose be given if necessary [76, 77]. Even though the American Academy of Pediatrics Committee on Infectious Diseases and the Centers for Disease Control and Prevention's (CDC) Advisory Committee on Immunization Practices (ACIP) advise against the use of this live vaccine in immunocompromised patients, accumulating data show that it could be safely administered in carefully selected SOT recipients [78, 79]. Hence, criteria for safe live vaccine administration after SOT have been published [80]. Where possible however, such vaccination should thus be provided, and protective antibody levels documented, prior to transplant [81–83].

Antiviral prophylaxis is not routinely recommended. First, patients receiving CMV prophylaxis will be indirectly prophylaxed against VZV given the efficacy of (val)ganciclovir on VZV. For patients not receiving CMV prophylaxis nor HSV prophylaxis, short-term prophylaxis against VZV using (val)aciclovir is recommended in VZV-seropositive patients [84].

Varicella-näive patients at the time of transplant (not immunized or did not respond to immunization) exposed to varicella should receive prophylactic therapy with varicella zoster immune globulin (VariZIG). The ACIP recommends that use of this product may be requested in immunocompromised patients exposed to varicella infection [85]. If this product is not available, intravenous immune globulin (IVIG), which contains some anti-varicella antibody, may be given [85]. Any prophylactic therapy should be given as soon as possible, up to 10 days after exposure [86]. Prophylactic aciclovir may be used after exposure, especially if the window for VariZIG has passed, though data are limited [86]. Patients who develop infection, either primary or secondary, should receive treatment with intravenous aciclovir [84, 87, 88]. Once lesions are improving, oral valaciclovir can be considered. In case of a mild localized (demartomal) zoster, initial treatment with oral valaciclovir can be considered [84].

BK Virus

The BK virus (BKV) was first isolated from the urine of a renal transplant recipient in the 1970s [89]. However, this virus did not represent a significant complication of kidney transplantation until the late 1990s [90, 91]. Though BKV is a polyoma virus, it shares some characteristics of the herpesviruses: (a) infecting most immunocompetent people during childhood; and (b) establishing a prolonged latency. Unlike the herpesviruses, the BK virus does not establish in the reticuloendothelial cells but prefers the uroepithelium. This propensity for the uroepithelium is responsible for the clinical manifestations: hemorrhagic cystitis in bone marrow transplant recipients and allograft nephropathy in kidney transplant recipients. The incidence of BKVAN in pediatric renal transplantation appears to be the same as in adult kidney transplants at 3–8% [5, 92]. Risk factors from adult kidney transplant data include the intensity of immunosuppression [93, 94], recent treatment for acute rejection [95] and placement of a ureteral stent [96], though the data implicating specific immunosuppressive agents is conflicting. In a multicenter North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) special study, use of antibody induction and zero mismatch kidney allografts were the only two risk factors for BKVAN in multivariate analysis [5].

BKV infection and BKV disease are two separate entities. Serial PCR surveillance has shown that urine PCRs turn positive earlier and much more often than peripheral blood PCR. The diagnosis of BKVAN depends on demonstration of the virus in blood or kidney tissue (either by PCR or immunostaining) and the presence of nephropathy (raised serum creatinine or tissue inflammation). Urine positivity without the other features represents infection without disease, as discussed in the recent guidelines for study monitoring by the American Society of Transplantation [97]. Generally, isolated viruria is not associated with renal dysfunction [98].

BKVAN represents a diagnostic challenge because the condition may resemble acute rejection. Symptoms are often minimal or absent. Serum creatinine elevations are found on clinical laboratory monitoring. Since the treatment of acute rejection (intensifying immunosuppression) is the opposite of the treatment of BKVAN (reduction in immunosuppression), making the correct diagnosis is critical.

Isolated BK viremia without nephropathy may not need treatment or may be manageable by reduction in immunosuppression. Like the CMV and EBV infections, reduction of immunosuppression is usually the first step in the treatment of full-fledged BKVAN [91, 99, 100]. However, by the time BKVAN is diagnosed, the serum creatinine is significantly raised and subsequent graft survival is worse. Antiviral therapy against BK virus is more complicated than for CMV or EBV, since neither aciclovir, ganciclovir, nor their analogues have activity against BK virus. Therefore many centers have tried alternative agents, given the impact of BKVAN upon allograft survival [101–105]. So far, no randomized studies have proven the benefit of either leflunomide, cidofovir, fluoroquinolones, or IVIG; consequently, these agents are not routinely recommended [97].

There is no vaccine against BK virus. Preventive strategies that have been suggested include serial urine or plasma BK PCR monitoring and preemptive reduction in immunosuppression. For all kidney transplant recipients, BK virus guidelines recommend monthly plasma monitoring until 9 months post-SOT, followed by monitoring every 3 months [26, 97].

Adenovirus

Adenovirus infections are common after kidney transplantation, with reported incidences of 4–7% in adults and 11% in children [106]. Clinical presentation can range from asymptomatic replication to organ disease such as hemorrhagic cystitis, hepatitis, pneumonia, or colitis [106]. Adenovirus infection frequently involves the graft, with graft dysfunction regularly reported. In case of adenovirus disease, the mainstay of the management is reduction of immunosuppression. For severe or disseminated disease not responding to reduction of immunosuppression, intravenous cidofovir should be considered despite the absence of randomized studies demonstrating its benefit [106].

Common Respiratory Viruses

Respiratory viruses are responsible for significant morbidity and mortality following pediatric transplantation. Despite an increased severity among transplant recipients, clinical presentation is usually similar to the general population [107].

Influenza virus infection is one of the most common respiratory viral infection and the only one for which an effective preventive strategy is widely available. Indeed, all transplant recipient should receive the inactivated tri- or quadrivalent influenza vaccine yearly [107]. In case of suspected or documented influenza infection, treatment with a neuraminidase inhibitor such as oseltamivir or zanamivir should be administered as soon as possible given the fact that early treatment has been associated with improved outcomes [107].

Other clinically relevant viruses in kidney transplantation are respiratory syncytial virus, parainfluenza virus, and human metapneumovirus. Unfortunately, no effective prevention strategies nor efficient treatments are available, even though ribavirin could be considered in specific situations [107].

SARS-CoV-2

The current pandemic has severely affected adult kidney transplant recipients, with fatality rates up to 28% [108]. This is higher than in recipients of other organs [109, 110] and likely related to the vascular comorbidities classically seen in kidney transplanted adults. So far, only a few cases of COVID-19 have been reported in pediatric kidney transplant recipients [109, 111, 112], and all had a relatively mild presentation, as seen in healthy children. It has been suggested that the immunosuppressive treatment may protect against severe SARS-CoV-2 infection by avoiding the hyperinflammatory state [113]. A document providing expert opinion regarding prevention, diagnosis, and management of SARS-CoV-2 infection among pediatric SOT candidates and recipients has been recently published [114].

Fungal Infections

In the SOT setting, the one-year cumulative incidence of invasive fungal infection (IFI) is around 3% [115]. However, with a one-year incidence of 1%, kidney transplant recipients are at lowest risk of IFI when compared to the other organ recipients [115]. Similarly, in the pediatric setting, IFIs are less common in pediatric kidney transplant recipients than thoracic organ recipients. Two studies reported a retrospective incidence of 4–10% overall (including milder *Candida* spp infections) in adult kidney transplant recipients [20, 116]. In studies restricted to the intensive care unit, the incidence is higher at 16.5% [117]. Among pediatric recipients, hospitalization for fungal infection represented 0.2–2.7% of all infection-related hospitalization in the NAPRTCS registry, but was associated with a 1.64-fold higher risk for graft loss [118].

Candida spp

Candida spp are the most common fungal organisms affecting kidney transplant recipients, either as oral thrush, vaginitis, nail infection, UTI, or rarely as systemic fungemia [119]. The diagnosis of thrush is made by clinical examination whereas candidal UTI is diagnosed by urine culture. Treatment for topical candida is by topical nystatin or clotrimazole and UTI is generally treated with fluconazole [120]. Invasive candida infection is responsible for 49% of IFIs in kidney transplantation [115] and is associated with significant mortality and morbidity [117]. Among *Candida* spp, *C. albicans* is most frequently responsible for IFI (42%), followed by *C. glabrata* (28%) and then other *Candida* spp. Treatment of Candida IFI usually with an echinocandin, with fluconazole and amphotericin being alternative options [120]. Given the overall low risk of Candida IFI after kidney transplantation, prophylaxis is generally performed for the first transplant month only by many centers. More prolonged prophylaxis may be considered in case of enteric drainage, vascular thrombosis, or postperfusion pancreatitis [120].

Aspergillus spp

Invasive aspergillosis (IA) is responsible for 14% of IFIs after kidney transplantation [115] and is reported in 1–4% of kidney transplant recipients [121]. Among *Aspergillus* spp, *A. fumigatus* is responsible for 75% of IA episodes documented after transplantation [121]. Moreover, about 75% of IA episodes are limited to the respiratory tract [121]. Risk factors for IA after kidney transplantation are a recent episode of acute rejection, graft failure, and dose and duration of exposure to steroids [121]. Voriconazole is the mainstay of IA's treatment. Anti-mold prophylaxis is currently not routinely recommended in kidney transplant recipients [121].

Pneumocystis

Infections with *Pneumocystis jirovecii* (previously known as *Pneumocystis carinii*) have fortunately become rarer with the widespread use of cotrimoxazole prophylaxis in the immediate post-transplant period. The diagnosis is established by demonstration of pneumocystis in lung secretions obtained from bronchoalveolar lavage or in tissue from lung [122]. Gomori stain or toluidine blue staining will demonstrate the cysts and Giemsa staining will identify the sporozoites. CMV infection is the major differential diagnosis. Many children may have dual infection, in which CMV infection predisposed to superadded pneumocystis pneumonia (PCP) infection. The antimicrobial agent cotrimoxazole (trimethoprim-sulfa) is the preferred treatment, with or without adjunctive steroids. Cotrimoxazole may be given either orally or intravenously and is less toxic, whereas the alternative pentamidine is only available as a parenteral or inhaled preparation and has more side effects. Chemoprophylaxis with three times a week oral cotrimoxazole (5 mg/kg trimethoprim component/dose) reduced the incidence of PCP disease from 3.7% to 0% [123]. Routine prophylaxis is recommended in all transplant recipients during the periods of high risk, typically the first 6–12 months post-transplant [124]. Some centers also advocate its use after anti-rejection therapy, particularly with anti-T cell antibodies. Some centers suggest a lower dose given daily at bedtime [125].

Parasitic Infections

Reports of parasitic infections in pediatric kidney recipients are few. *Strongyloides stercoralis* is an intestinal nematode with worldwide distribution, endemic in tropical/sub-tropical regions, and infects tens of millions of people. The southeast part has the highest incidence within the United States [126]. Similar to viruses, *S. stercoralis* may initially remain in the human intestinal tract without symptoms, and then disseminate with the introduction of immunosuppressive medication post-transplant [126, 127]. In addition strongyloidiasis transmission has been reported through the allograft kidney in an adult recipient [128]. Among calcineuirn inhibitors, cyclosporine (but not tacrolimus) has effects against *S. stercoralis* and may reduce the risk for disseminated strongyloidiasis [129, 130]. Active infection manifests with cutaneous, gastrointestinal and pulmonary symptoms as well as eosinophilia [131]. Fever, hypotension, and central nervous system symptoms suggest dissemination [131]. In uncomplicated infections, diagnosis is made by detection of larvae in stool, although 25% of infected patients may have negative stool examinations [132]. In disseminated disease, larvae may be found in stool, sputum, bronchoalveolar lavage fluid, and peritoneal and pleural fluid [126, 133]. Serologic testing using ELISA may also be of value, although may be falsely negative in immunocompromised hosts [133]. Ivermectin has replaced thiabendazole as the treatment of choice for *S. stercoralis,* with albendazole as an alternative [134].

Other parasitic infections that have been transmitted by the renal allograft include Chagas' disease [135] and post-transplant malaria [136]. Chagas' disease (caused by *Trypanosoma cruzi*) is found only in the southern United States, Mexico, and Central and South America. The manifestations of Chagas' disease classically include megaesophagus, megacolon, and cardiac disease, although CNS involvement has been reported in kidney transplant recipients [135]. The diagnosis is serological and treatment typically consists of benznidazole or nifurtimox. Post-transplant malaria can be frequent in high-endemic areas, so suspicion clinically should be based on local region or travel to such a region [136]. Screening recipients and donors for these and other parasitic infections may be worthwhile, based on the presence of risk factors including residence in or travel to an endemic area (Tables 1 and 2).

Abstract

Kidney transplantation is the best option for renal replacement therapy in nearly all children, but it comes with short- and long-term complications. Noninfectious transplant-related comorbidities largely originate from the specific side effects of immunosuppressive therapy and chronic kidney disease (CKD)-related problems caused by impaired graft function. Recurrent cramps from hypomagnesemia, hypertension, anemia, persistent growth retardation, tremors, cosmetic changes, and gastrointestinal problems are among the most common short-term side effects. Urological problems often occur and may severely impact graft survival. Calcineurin inhibitors-induced

posterior reversible encephalopathy syndrome and post-transplant lymphoproliferative disease (PTLD) are rare, but may cause severe short-term complications. Post-transplant lymphoproliferative disorder (PTLD) is more prevalent in pediatric than in adult graft recipients. Post-transplant diabetes and dyslipidemia are less prevalent than in adults. Quality of life improves after transplantation coming from chronic dialysis treatment, according to most, but not all reports. Cognitive dysfunction is a common feature and may have an important impact on the quality of life.

Late complications into adulthood include a high risk for malignancies, especially for severe forms of squamous cell skin carcinoma. Additionally, cardiovascular disease, chronic joint pain and motor disabilities, and chronic fatigue. Cognitive impairment and delayed autonomy are associated social problems concerning sexual relationships, obtaining a paid profession, and starting a family. Despite these problems, long-term survivors of kidney transplantation consider their quality of life on average as good, especially with respect to mental domains.

Non-infectious · Complications · Late outcome

Introduction

]Kidney transplantation is by far the best therapeutic option for children with end stage kidney disease (ESKD), but it is not curative of the disease. It comes with its own problems, induced by side effects of immunosuppressive therapy and the often limited graft function. Infection is the most common and life-threatening comorbidity, and is separately discussed in ► Chap. 83, "Renal Transplantation: Infectious Complications". Also, surgical complications, recurrence of primary disease, and chronic rejection are discussed elsewhere. In this chapter, we will first discuss the impact of pediatric kidney transplantation on somatic comorbidities other than infection, including cognitive development and psychosocial functioning in childhood. Finally, we will review what is currently known about late outcomes of pediatric kidney transplant recipients and the perspectives of transplanted patients in childhood on adult life with respect to somatic condition, related disease, and psychosocial functioning.

Short- and Medium-Term Complications

Introduction. Cramps by hypomagnesemia, most often related to the use of calcineurin inhibitors (CNI), chronic fatigue, and MMF-related gastrointestinal symptoms (pain, nausea, diarrhea) are the most often reported complaints after transplantation. Calcineurin inhibitor-induced tremors and headaches occur more rarely, but can be seriously disabling. Table 1 summarizes frequent and less common noninfectious somatic problems that are associated with kidney transplantation and its therapy. In this part, we will discuss in more detail the most important comorbidities and psychosocial consequences of kidney transplantation in children.

Hypertension

Epidemiology. Hypertension (HTN) is probably the most important modifiable risk factor for the development of life-threatening cardiovascular disease (CVD) in CKD5. As CVD is the second most common cause of death after kidney transplantation, early and maintained management of HTN is of utmost important [1]. Like in adults, HTN is also associated with shortened graft survival [1–4]. In one study, there was a two-fold higher risk of graft loss for each 10% increase in systolic blood pressure (BP) at 1 year after transplantation [4].

Yet, data on current practice show that control of HTN remains a challenge, not only in dialysis but also after kidney transplantation. Both US and European Registry studies show that uncontrolled

Table 1 Frequent early onset comorbidity of kidney transplantation in children

Complication		Frequency	Association	Impact
Cardiovascular disease	Hypertension	High	Pred, CI, graft dysfunction	Early graft loss, early mortality, impaired QOL
	Dyslipidemia	Moderate	Pred, mTORi	
	Obesity/metabolic syndrome	High	Pred	
	Post-tx diabetes mellitus	Low	CI + pred[a]	
Bone disease	Osteoporosis	High	Pred, immobility	Fractures, pain, motor disability, psychosocial impact of short stature
	CKD-MBD	Moderate	Graft dysfunction[b]

[a] High in case of steroid/CsA maintenance regimen[e]

[b] Impaired Ca/Pi/PTH management

HTN is highly prevalent in dialysis patients, but also persists in 21% of patients after kidney transplantation [5, 6]. Less than 30% of the transplanted patients in the ESPN registry had a normal BP without antihypertensive medication and more than 50% had BPs higher than the 75th percentile [5]. A UK registry study even showed an increase in uncontrolled HTN prevalence from 28% at time of transplantation to 50% after 2 years of follow-up [7]. A Dutch study found 38.3% uncontrolled HTN after kidney transplantation in patients aged <19 years and nearly 76% in patients aged 18–30 years [8]. HTN is probably underreported in these studies, as the prevalence of masked HTN – HTN found by 24-h ambulatory BP monitoring (ABPM) but not by office BP measurement – is higher among pediatric transplant recipients than found in any other pediatric cohort. Masked HTN may occur in up to 38% of patients and the majority of transplanted children have no adequate nocturnal dipping [9]. Data of the 4C study showed that nocturnal HTN was associated with an increased risk of subclinical CVD in children, as measured by surrogate outcomes markers [10].

Causes. There are three main sources of transplantation-related factors that may lead to HTN: (1) condition of the donor graft, (2) immunosuppressive therapy, and (3) de novo graft injury. Donor-associated factors include older donor age, small donor kidney size, preexisting donor HTN, and, above all, poor allograft quality [11]. Donor quality has been long recognized to be a significant contributor to post-transplant HTN. Recipients of the so-called extended criteria donors are especially at risk known for post-transplant HTN [12].

Transplant renal artery stenosis (TRAS) is a relative rare, but important cause of HTN after kidney transplantation. In adults, TRAS affects long-term graft survival, independent from the HTN that is concurrently induced [13]. Data in children are scarce, but the reported incidence of about 4–6% seems in line with adult reports [14–17]. In general, transplant renal artery stenosis should be considered in case of severe, therapy resistant HTN. In an Italian study of 10 cases among 216 pediatric kidney graft recipients, patients with renal artery stenosis required on average more antihypertensive medication than those with HTN for other reasons. Four out of ten had vascular abnormalities or complications during surgery. All were detected by Doppler ultrasonography [16]. Both delayed graft function or long ischemia time and cytomegalovirus (CMV) infection have found to be predictive for TRAS in adults [13].

Some genetic variants, either of the recipient or the donor are associated with subsequent post-transplant HTN. The role of variations in the apolipoprotein L1 gene (*APOL1*), as often is found in African-Americans, is complex with respect to post-transplant HTN. There is evidence that donors with two specific APOL1 gene variations in donor kidneys strongly predispose to the development of nephropathy, also post-transplant and subsequently to early graft loss and concurrent HTN, secondary to the nephropathy [18]. This particular gene variation is a stronger risk factor for early graft failure and parallel occurring HTN than any other known risk factor such as HLSA mismatch, expanded donation criteria, long cold ischemia time, or positive PRA [19]. The fact that African-American donor kidneys with less than two *APOL1* risk variants have equal outcomes to that of kidneys from European American donors shows that race per se is not the driving factor.

Steroids and calcineurin inhibitors are the most responsible immunosuppressive drugs for HTN. Cyclosporine induces sodium retention most likely as a result of afferent glomerular arteriolar vasoconstriction. Tacrolimus also leads to salt retention, but may be less associated with HTN than cyclosporine. Acute and chronic rejection and TMA are most common factors leading to de novo or worsening of existing HTN. Younger age, obesity, male gender, and high salt intake are the most important recipient-related factors contributing to HTN [20].

Management. Unfortunately, the evidence that adequate BP control is indeed beneficial for transplanted children with respect to graft survival and cardiovascular protection is limited. Seeman et al. showed in a prospective interventional study with intention to treat analysis that aggressive management of HT was associated with significantly less loss of estimated glomerular filtration rate (eGFR) after 2 years of observation [21]. However, in the ESCORT trial, no benefit was found from intensified BP control with respect to graft survival [22, 23]. The ESCAPE study showed improvement in surrogate outcome markers for CVD with angiotensin-converting enzyme inhibitors (ACEi) use in hypertensive children with CKD 2–4 [23], but only one small study showed similar results in transplanted children. Despite the paucity of evidence, Kidney Disease: Improving Global Outcomes (KDIGO) guidelines advise maintaining BP at below the 90th percentile for age, height, and gender (evidence level 2C) [24]. Steroid removal or reduction, in case of maintenance steroid immunosuppressive regimens, should be considered the first step. Salt restriction and prevention of obesity are also extremely important first-line measures. In the early post-transplant period, volume and salt overload often dominate, in which case a diuretic is the drug of choice. It is generally recommended that ACEi are avoided in the early period after transplantation due to its acute impact on eGFR and risk for hyperkalemia. In the longer run, calcium channel blockers (CCBs) and ACEi are currently the most used antihypertensive drugs after kidney transplantation. The preferable choice is under debate, but most meta-analyses recommend CCBs as first choice due to their positive effect on graft function and survival and lack of hyperkalemia and anemia as side effects. The presence of overt proteinuria might be a reason to choose ACEi as first choice. As HTN control can be difficult and several studies have shown that combining two or three anti hypertensive drugs can be very effective, a combination of CCB and ACEi could be a good solution for more severe HTN after transplantation. With the prescription of ACEi or ARB, the enhanced effect of CNI, mammalian target of rapamycin (mTOR) inhibitors, and cotrimoxazole on the hyperkalemic side effect – especially if eGFR declines – must be taken into consideration. There is increasing evidence that, especially in transplanted children, ABPM has an important role in monitoring adequate BP control, even more than in adults.

PTA is in over 80% of cases effective in reducing the BP in patients with transplant renal artery stenosis [13, 16]. Contrary to the non-transplanted situation, there is no consensus in the literature about the degree of arterial narrowing that would justify angioplasty, but generally, lesions causing arterial diameter stenosis of >50% assessed by angiography are considered to be hemodynamically relevant [16].

Dyslipidemia

Dyslipidemia is less frequent in pediatric transplanted patients than in dialysis patients, but may still contribute in many to cardiovascular morbidity and mortality. Among transplant recipients ($N = 564$) in the ESPN registry, 55.5% had some form of dyslipidemia, based on levels defined as “too high” by an expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents [25–27]. Eighty-eight percent of transplant recipients in the Certain registry had dyslipidemia defined as either “borderline high” or “high at 1 year post-transplantation [28].

Cyclosporine, steroids, and, most of all, mTORi have a relatively unfavorable profile, compared to tacrolimus (TAC) and mycophenolate mofetil (MPA) [25, 27, 28]. Regimens with cyclosporine, steroids, and mycophenolic acid (MPA) are associated with a 3- and 25-fold ($P < 0.001$) increased risk of having more than one pathologic lipid parameter as compared to the use of TAC, MPA, and steroids [28]. In a meta-analysis of adult kidney transplant recipients, the use of sirolimus was associated with a higher risk for dyslipidemia than any calcineurin inhibitor [29].

Post-transplant dyslipidemia may occur in various types. The use of cyclosporine instead of TAC may result in higher triglyceride and non-HDL levels in children as well as in adults [28, 30]. Steroid use is associated with higher triglyceride and non-HDL levels, the use of mTORi predominantly with higher non-HDL levels. In adult literature, no difference in lipid profile was found between the use of azathioprine versus MPA. The data in the pediatric literature are inconclusive [28, 30]. Other risk factors are a low eGFR and post-transplant diabetes mellitus. Despite the potential added cardiovascular risk, statin therapy is not recommended by KDIGO as hard evidence for its benefit and long-term safety is lacking. Adjustment of immunosuppressive therapy (cessation of steroids, avoidance of cyclosporine) and moreover nutritional counseling and lifestyle improvement are the most important interventions recommended [31].

Post-Transplantation Lymphoproliferative Disorder (PTLD)

The term post-transplantation lymphoproliferative disorder (PTLD) represents different types of lymphoid neoplasms that may develop after kidney organ transplantation. The World Health Organization (WHO) divides PTLD into four subtypes: an early, a polymorphic, a monomorphic, and a classical Hodgkin-lymphoma-like type (Table 1), each with its different therapeutic approach. PTLD may occur at any time after transplantation, but the highest incidence is within the first year after transplantation. These so-called early onset PTLD types are for 95% associated with Epstein-Barr virus (EBV) and have a relatively good prognosis [32].

Epidemiology and prognosis. PTLD complicates 0.8–20% of transplant recipients, about 0.8–2.8% in kidney transplant recipients [32–34]. The incidence is higher in patients receiving heart, lung, small bowel transplant, or combined heart-lung transplant than in kidney transplant recipients, which reflects the impact of the immunesuppression dosage [32]. Donor EBV-seropositive/recipient EBV-seronegative status, duration of immunosuppression, and status of EBV infection are the most important risk factors. Early-onset PTLD mostly occurs in the setting of EBV seropositivity and reactivation from latent B-cells as a consequence of immunosuppressive therapy (Table 2). The situation of an EBV-seronegative

Table 2 Late complications and potential preventive measures

Complication		Cause	Prevention
	Cardiovascular disease & mortality	Graft dysfunction, hypertension, dyslipidemia, dialysis years, calcineurin inhibitors	Vigorous control of blood pressure & dyslipidemia
	Motor disabilities	CKD-MBD, steroids, immobilization	Avoiding steroid maintenance therapy Ca/Pi/PTH/Vit. D management Consider bisphosphonates
	Cancer	Immunosuppressive therapy, UV, viral infection (EBV, papilloma)	Sun protection Papilloma vaccination (?) Vigorous EBV monitoring Tailoring of immunosuppressive therapy
	Infections	Immunosuppressive therapy	Tailoring immunosuppressive therapy, pre-tx vaccination
	Delayed autonomy development	Social deprivation by hospitalization and overprotection, cognitive impairment, physical strain	Active management toward autonomy at adolescence Avoidance of “overprotection”

recipient getting an allograft from an EBV-seropositive donor (D+/R−) may lead to a primary EBV infection, which is the most important risk factor for developing PTLD. This is why PTLD occurs two to eight times more often in pediatric than adult transplant recipients [35, 36]. The time from transplantation to PTLD diagnosis ranges from 6 months to 7 years and shows a biphasic pattern [36]. Late onset PTLD is most often not related to EBV but to the impact of relative high burden of immunosuppressive therapy and has an overall worse prognosis than the early onset form [36, 37].

Pathophysiology of EBV-associated PTLD. EBV is a lymphotropic virus which enters the B-lymphocytes during the initial infection and remains in the host nucleus in a state of latency for that individual's lifetime. This latent state is associated with EB nuclear antigen production and Latent Membrane Proteins, which protect the B-cell from apoptosis and stimulate ongoing viral replication that is controlled by a cytotoxic T-cell-driven EB-specific surveillance. Impairment of this cytotoxic T-cell protection is believed to be essential for developing PTLD [38]. Lack of T-cell protection leads to uncontrolled viral replication and an increase of virus-carrying B-cells in the circulation [38]. Cytokine responses, induced by immunosuppression, may lead to uncontrolled B-cell proliferation and ultimately neoplastic PTLD.

Monitoring and early detection. Elevated levels of EBV in mononuclear cells or in plasma by PCR is the key to an early detection of PTLD. Serial EBV quantitative PCR levels are the most important monitor as rising levels are more predictive than a single positive EBV quantitative PCR. EBV+ PTLD can arise at any time after transplantation, but the incidence is highest in the first 1–2 years post-transplant, so monitoring should be frequent during this period [39]. Unfortunately, there is currently no standardized assay for EBV quantitation and multiple PCR-based platforms have been used. Thresholds for elevation of the EBV load are therefore established by individual labs [39]. A negative EBV PCR does not exclude the possibility of PTLD. Unexplained anemia, thrombocytopenia or leukopenia, and high LDH and uric acid levels are non-specific generic abnormalities, associated with PTLD or another malignant blood or lymph disease. Patients should be carefully checked for tonsillar hypertrophy; if they do occur, a biopsy is indicated. Radiological monitoring includes MRI, CT, and positive positron emission tomography (PET) scanning to evaluate the spread of PTLD. In case of CNS involvement, a lumbar puncture with cerebral spinal fluid (CSF) analysis (EBV PCR in CSF fluid) is indicated. Histopathologic examination of the tumor can only determine the definitive diagnosis.

A new development in the monitoring process is the detection of a certain viral load as proxy for decrease of immuno-competence [40]. Analyses in 96 heart and lung transplant recipients suggest that high levels of anellovirus load may be indicative of over-immunosuppression. In line with this, metagenomic shotgun sequencing of tissues from PTLD patients showed that more than 50% of the specimens contained anellovirus sequences, and the anellovirus levels, but not EBV levels, were associated with death within 5 years in a univariate analysis [41]. This presumes that virome changes, and even specific viruses such as anellovirus, may provide indirect measures of the immune status, which can promote the development of EBV+ PTLD.

Therapy/prevention of PTLD. The first step in the prevention of PTLD is reduction of immunosuppressive therapy in case of an increase in EBV load in EBV-seronegative recipients and incase of EBV disease in all recipients (KDIGO level 2D and 1C) [24]. Rituximab is the cornerstone of 1e first-line therapy of PTLD. In a multicenter trial, all 152 transplant recipients with CD20+ PTLD, unresponsive to immunosuppression reduction, were first treated with four doses of weekly rituximab. In case of complete remission, treatment with rituximab was continued with another four doses of rituximab, other patients received four R-CHOP courses. The overall response and CR rates were 88% and 70%, respectively; the response to the first four courses of rituximab was the most significant prognostic factor with respect to overall survival and time to progression [42].

Post-Transplant Diabetes Mellitus

Hyperglycemia and post-transplant diabetes mellitus (PTDM) are serious complications of kidney transplantation [43]. Hyperglycemia is very common in the early post-transplant period, with approximately 90% of adult kidney recipients exhibiting hyperglycemia in the first weeks after transplant. The development of PTDM is associated with reduced graft function, increased cardiovascular disease, higher rates of rehospitalization, and lower patient survival among adult recipients [44, 45].

PTDM is highly prevalent in adult kidney transplant recipients [46], but is less common in transplanted children according to a retrospective analysis of the NAPRTCS registry. The reported incidence of PTDM was reported at 2.6% (2). More recent retrospective studies reported higher incidences of 8–13% [47, 48]. The American Diabetes Association (ADA) criterion has defined criteria for PTDM [43]. Risk factors for PTDM include traditional general diabetes risk along with transplant-associated risk factors that include immunosuppressive medications.

The prevalence of obesity in children is rising and remains a concern among health care providers as it is a recognized cardiovascular risk factor. Nearly one in five school-aged children in the United States has obesity and this may contribute to PTDM [49]. Bondi described a cumulative incidence of obesity at 5 years post-transplant in nearly 25% of all transplant recipients, with pediatric kidney transplant recipients having the highest risk with a 3.13 adjusted hazards ratio [50]. The risk factors for obesity appear to be young age, overweight at the time of transplant, race, and relative high cumulative steroids use [50, 51].

Additionally, glucocorticoids, mTORi, and CNI are known risk factors, and support's individualized immunosuppression regimens in select patient populations [51]. Glycemic effects of glucocorticoids are thought to be dose and duration dependent, with higher doses of glucocorticoids in the first 6 months being a particular risk factor based on NAPRTCS data [52]. CNI are directly toxic to the islet cells and impair insulin gene expression and insulin secretion [51]. Studies have demonstrated tacrolimus and sirolimus as independent risk factors for PTDM. Changing to cyclosporine or belatacept has been shown to improve or resolve diabetes without graft compromise in adults [51, 53]. The effects are dose related and may be partially reversible [54, 55].

The gold standard test for the diagnosis of PTDM is the oral glucose tolerance test, but screening hemoglobin A1c and fasting blood glucose values can identify high risk patients. The diagnosis of PTDM is optimally made when patients are on a stable immunosuppressive regimen and without infection [43]. Treatment of PTDM should follow the ADA guidelines with overall multifactorial management that includes lifestyle modification, alternative immunosuppressive regimens, and pharmacologic intervention [43]. Insulin is often the first-line therapy as oral antihyperglycemic agents have limited safety and efficacy data in pediatric kidney transplant recipients with PTDM [56].

Bone Disease Following Transplantation and Growth

Bone Health

Mineral bone disease after kidney transplantation is a spectrum of bone abnormalities related to CKD and the use of corticosteroids. The process starts early in CKD and assessing bone health is a key element of managing kidney transplant recipients; CKD-related bone disease is described at length in ▶ Chap. 72, "Chronic Kidney Disease – Mineral and Bone Disorder (CKD-MBD)". Post-transplant mineral bone disease is often due to preexisting CKD-MBD, glucocorticoids, and reduced allograft function [57]. Dysregulation of the pathways responsible for bone health can lead to bone demineralization, short stature, pain, deformities, and anomalous calcifications [58].

Biochemical anomalies can be seen in calcium, phosphate, parathyroid hormone (PTH), 25-hydroxy vitamin D, 1,25-dihydroxyvitamin D, alkaline phosphatase, and Fibroblast Growth Factor (FGF) 23 in pediatric kidney transplant recipients [58]. Analysis of the European Society for Paediatric Nephrology/European Renal Association-European

Dialysis and Transplant Association Registry demonstrated many abnormalities in pediatric kidney transplant recipients. Abnormal serum phosphorus levels were seen in 25%, serum calcium in 30%, and hyperparathyroidism in 41% of the recipients [59]. Persistent elevations in PTH and FGF23 may cause hypophosphatemia and resulting impaired bone mineralization [57]. The risk for fracture and impact on bone density has not been widely studied in pediatric patients and data is limited [60].

Additional risks for bone mineral disease appear to be related to racial differences among pediatric kidney transplant recipients related to bone disease. Black race was associated with 20–25% higher PTH values and lower bone density in chronic kidney disease and kidney transplant recipients [61, 62]. Hispanic race was associated with a 17.5% higher PTH and 16% lower C terminal FGF323 values compared to white chronic kidney disease and dialysis patients [62, 63]. The studies in pediatric kidney transplant recipients and racial differences have been limited and more data is needed.

Growth

Growth failure is a commonly observed complication of ESKD largely due to deficiency, resulting in pediatric kidney transplant recipients needing to grow. The NAPRTCS registry has estimated the height deficit at the time of transplant to be −1.8 [64], which is in line with European data. The greatest risk factors are relative older age at time of transplant, allograft dysfunction, and corticosteroid use [65–67]. Younger children, less than 5 years of age, can demonstrate catch-up growth, but older children rarely demonstrate catch-up growth [66].

Sustained growth failure remains common after renal transplantation as a result of glucocorticoid therapy and renal impairment [65]. Steroid avoidance demonstrates particular improvements in height standard deviation score (HSDS) in the first year after steroid withdrawal and in prepubertal patients [67]. Reducing or avoiding corticosteroid therapy can be safe in select kidney transplant recipients and will have beneficial impact on linear growth [67, 68].

The safety of growth hormone therapy had been a concern in pediatric kidney transplant recipients in the 1990s. Recent work has shown that growth hormone is safe and efficacious with an improved HSDS of 0.68 in transplant recipients receiving growth hormone compared to controls [69, 70].

Urologic Complications

Urological complications have significant impact on cost and frequent hospitalizations in the post-transplant period. The incidence was higher in children with a history of cystoplasty and preexisting urologic surgeries/anomalies [71, 72]. With approximately 25% of children undergoing kidney transplantation having anatomic abnormalities of the lower urinary tract, urologic complications remain a major concern [73].

Ureteral Obstruction

Risk factors for ureteral obstruction are not well understood, but contributing factors include surgical expertise, decreased vascularity of the donor ureter, and rejection [74]. Early ureteric obstruction is usually related to potential surgical complications, such as lymphocele or hematoma. The frequency of surgical complications has reduced from 30% to around 10% with improvements in donor extraction, preservation of vasculature, and use of a shorter ureter [75, 76].

Causes of obstructions that occur after 1-month post-transplant are more elusive. Adult literature suggests that obstruction at the uretero-vesicular junction is most susceptible to ischemic injury as the vascular supply is derived from the donor renal hilum. Mid- and uretero-pelvic junction obstruction is more commonly related to rejection with localized ischemic injury [72].

BK virus (BKV) is a common polyoma virus with seropositivity in 60–90% of the general adult population [77, 78]. In kidney transplant recipients, BKV can reactivate and cause viruria, nephropathy, ureteral ulceration and stenosis, interstitial nephritis, and, rarely, hemorrhagic cystitis [78, 79]. The risk factors for ureteric stenosis and BK reactivation are thought to include active

BK infection in the donor, ischemic injury, immune control, and delayed graft function [78, 80].

Dysfunctional Lower Urinary Tract

Transplantation using a dysfunctional bladder is associated with many urologic complications. These urologic complications may negatively affect graft survival, although results are mixed in the literature [81–86]. Careful surveillance through urodynamics and urologic care are likely needed to optimize these outcomes.

Success with bladder augmentation and ileal conduit diversion have demonstrated good short- and medium-term results, despite non-standard drainage, in more severe cases of lower urinary tract dysfunction [87–89]. If no intervention is conducted for severe bladder dysfunction, clean intermittent catheterization has been shown to be safe and effective [90]. Urinary tract infections and ureteral complications remain one of the leading complications when transplanting into a dysfunctional lower urinary tract [87, 91].

Urinary Tract Infections

Urinary tract infections (UTI) are the most common bacterial infection in kidney transplant recipients in both adults and children and are the leading cause of hospitalization in children [92–94]. Although UTIs can occur anytime in the postoperative period, it is most likely to occur in the first 3–6 months [95]. Transplant-specific risk factors include the presence of urethral stent, vesicoureteral reflux (VUR), episodes of acute cellular rejection, receipt of a deceased donor transplant, duration of hemodialysis, history of UTI prior to transplantation, and potentially antithymocyte globulin induction [95].

Early febrile UTIs, within the first 6 months of transplant, are associated with higher rates of graft loss and patient death based on data from the United States Renal Data System (USRDS) [96]. Patients with lower urinary tract dysfunction, females, and patients with urologic disease as their cause of kidney failure are at particularly higher risk of UTIs [84, 97]. Most kidney transplant recipients receive trimethoprim/sulfamethoxazole (TMP/SMX) as primary antimicrobial prophylaxis for *Pneumocystis jirovecii* pneumonia (PJP) for the first 6–12 months. TMP/SMX is also effective at preventing UTIs, but is usually used at higher doses than traditional PJP prophylaxis. The American Society of Transplantation Infectious Disease Community of Practice recommends utilizing doses for PJP prophylaxis as opposed to UTI prophylaxis given the risks for renal dysfunction and hyperkalemia with TMP/SMX. For patients who cannot tolerate TMP/SMX, 1 month of nitrofurantoin prophylaxis or cephalosporins is recommended [95].

The approach to recurrent urinary tract infections involves assessment of the underlying etiology and targeting prevention. Evaluation should include assessment of post-void residual bladder volumes and ultrasonography of the kidney and bladder to assess for structural anomalies. If no anomalies are present, a voiding cysto-urethrogram is recommended [95]. Patients should be reminded of basic infection prevention measures that include hydration, regular voiding, wiping front to back in females, avoiding bubble baths, and voiding after sexual intercourse.

Depending on the transplant surgeon, the use of anti-reflux surgery technique may or may not be done at the time of ureteral anastomosis for fear of creating a secondary renal obstruction. In fact, the adult literature supports a high rate of vesicoureteral reflux (VUR) post-transplant at 41% [98].

The incidence of VUR in pediatric kidney transplant recipients is not well studied, but seems to be higher than in adults. Single center studies found an incidence of symptomatic VUR to be between 4% and 12% and patients with underlying bladder pathology were at higher risk for developing VUR [73, 91, 99].

Surgical revision of the vesicoureteral anastomosis can be challenging due to scar tissue at the bladder and the tenuous vasculature of the transplanted ureter. Surgical intervention should be reserved for those who are having recurrent, febrile UTIs [99, 100]. Afebrile UTIs associated with vesicoureteral reflux can be managed with bladder training, hygiene, and/or antimicrobial prophylaxis [100]. Lengthening the submucosal tunnel and ureteral reimplantation have been shown to effectively improve or resolve VUR in pediatric kidney transplant recipients, but the impact on GFR decline may not be as impactful as initially thought [91, 101].

Gastrointestinal Complications

Gastrointestinal pain, diarrhea, and vomiting induced by mycophenolate mofetil is one of the most common early complications after transplantation. Spreading the dosage to three times per day or switching to enteric-coated mycophenolate can be effective in reducing these side effects with equal immunosuppressive efficacy [102]. Patients treated with tacrolimus are significantly more likely than those receiving cyclosporine to suffer dyspepsia, vomiting, diarrhea, and hypomagnesemia [103].

Cosmetic Complications

Cosmetic side effects of immunosuppressive therapy are among the most underrated complications of solid organ transplantation in children, especially in adolescents. Hirsutism and gingival hypertrophy induced by cyclosporine (and further enhanced by calcium channel blockers) in combination with the cushingoid side effects of steroids have often induced serious depression in many adolescents and caused a significant nonadherence to the therapy with subsequent graft loss [104]. The recent steroid-free, tacrolimus-based regimens have largely dealt with this problem, although tacrolimus-induced alopecia can also be a serious side effect.

Thrombotic Microangiopathy

De novo thrombotic microangiopathy (TMA) is a rare complication following transplantation. Reported rates are from 1.1% to 14% in adults. Allograft biopsy is always the gold standard of diagnosis. Pathology defines TMA as glomerular, arteriolar, or interlobular artery lesions characterized by patchy distribution with intimal cell proliferation, thickening, and necrosis of the wall, thrombi, and luminal narrowing [105].

TMA has heterogeneous manifestations in the post-transplant setting and is a complex and challenging process. De novo TMA may appear localized or systemic; localized TMA is only detected by biopsy and may lead to slowly chronic deterioration of graft function whereas systemic TMA may lead in the early postoperative period to rapid graft loss [106]. Even in systemic TMA, these systemic sequelae are relatively mild compared to non-transplant TMA and include features of hemolytic anemia, thrombocytopenia, and schistocytes.

De novo TMA may be secondary to calcineurin inhibitor treatment, mTORi, and infections, and antibody-mediated rejection [107–109]. ABO-incompatible kidney transplantation is an independent risk factor even after desensitization [106]. There are limited studies in pediatric kidney transplant recipients regarding TMA. In case reports of de novo TMA from the adult and pediatric literature, TMA was successfully treated with conversion from calcineurin inhibitors to alternative immunosuppression [110–112].

Neurological Complications

Neurological complications are common in adults after solid organ transplantation with a reported prevalence varying from 10% to 59% [113]. The reports in children are scarce and the prevalence seems to be lower than in adults, but far from absent. Neurotoxicity of immunosuppressive drugs, especially of calcineurin inhibitors accounts for most neurological complications. Clinical features may vary from tremors (up to 55% of patients), paresthesia, and seizures up to severe conditions like disabling pain syndrome and posterior reversible encephalopathy syndrome (PRES). Calcineurin-related PRES in older literature is often described as leukoencephalopathy and has also been reported in children [114, 115]. It presents as rapid onset of confusion, decreased level of consciousness, severe headaches, hyperreflexia, visual changes or seizures, and typical posterior white matter edema on imaging. Dysregulation of the cerebral perfusion and endothelial dysfunction have been linked to PRES. CNS toxicity is not related to plasma levels of cyclosporine or tacrolimus levels and children younger than 6 years of age seem more vulnerable for cyclosporine-associated neuropathy [116]. Tacrolimus seems to induce even more neurotoxicity than cyclosporine in adults [103], but data in children is lacking. Peripheral neuropathy is often seen in adults but may also occur in children [117]. It is most prevalent in chronic dialysis patients, but it may persist after transplantation. A neurophysiological study on 31 kidney transplanted children and adolescents showed that 19% of patients had neuropathic changes and that graft dysfunction and anemia were associated factors [118].

Quality of Life

Kidney transplantation increases life expectancy and much research has been conducted on medical outcomes in pediatric kidney transplantation. It has been presumed that the improved life expectancy improves quality of life (QOL) for children with ESKD, but the sequelae of transplantation and its treatment can make it difficult for transplant recipients to have similar quality of life to their peers. Data on health-related quality of life (HRQOL) of kidney transplanted children are conflicting. In a Dutch-Belgian-German study on 42 dialysis and 150 transplanted children, both dialysis and transplanted children scored significantly lower scores on all domains, except for emotional in the preemptively transplanted group. Preemptively transplanted patients scored higher on physical domains, but not on other mental domains. School functioning was equally low in dialysis and transplanted patients, even in preemptively transplanted patients [119]. A study in 26 Australian kidney transplanted adolescents reported overall good HRQOL, but with remarkable decrements in cognitive functioning and emotion [120]. Others confirm that preadolescents seem to report low HRQOL than adolescents after transplantation. Other important risk factors are neurological comorbidity, shorter follow-up time, and family-related variables. The latter stresses the potential need for family interventions in certain patients [121]. Like many things, QOL is subjective and some transplant recipients did not feel transplantation provided the picture of wellness they were expecting [122]. The conclusion is that restoring an organ function does not necessarily restore a “normal life” in children. Young adults who have experienced ESKD, even those who underwent kidney transplantation, were noted to have a variety of perceived challenges. These include a desire for normality, disrupted or modified ambitions, and a sense of uncertainty [123]. Despite the health benefits of transplantation, ESKD seriously affects QOL of children, even after transplantation.

Peer and Family

Compared to their peers, pediatric kidney transplant recipients are three times as likely to live in the family home compared to the general population and less likely to be married or live with a partner [122, 123]. Young adults are reluctant to share their medical condition with peers for fear of rejection or being considered “abnormal” [122, 124]. Many express body image issues related to their scars and medication side-effects (e.g., weight gain and hirsutism). They feel shame over being different and develop a degree of social isolation [123].

Education and Employment

Adults with ESKD have delayed education compared to peers, negatively impacting education [124–126]. Children under 12 years of age when diagnosed with ESKD had more difficult educational achievements compared to those who developed ESKD after puberty [124]. Children with ESKD were less likely to complete high school or higher education compared to peers [126–128]. Cultural differences may also impact QOL in school functioning, with non-Western origin transplant recipients in one study having higher risk of impaired school functioning compared to Western countries [129]. Additionally, young adults transplanted as children are less likely to have a job compared to the general population and adults who developed ESKD [122–126].

Cognitive Functioning

Cognitive impairment has for long been recognized as an important comorbidity of severe CKD and has particularly been linked to chronic dialysis treatment. The Neurocognitive Assessment and Magnetic Resonance Imaging Analysis of Children and Young Adults with Chronic Kidney Disease (NiCK) workgroup found significantly poorer performance of cognitive performance, particularly with respect to attention, memory, and inhibitory control among patients with CKD aged 8–25 years, compared to healthy controls [130]. The extent of decrease in eGFR, and increased diastolic BP load were independent predictors for low performance. There is evidence for anatomic substrate for functional brain impairment as has been assessed in patients with severe kidney dysfunction. White and gray matter brain atrophy assessed by CT and nonquantitative MRI has previously been described in young CKD patients and in particular in dialysis patients [131, 132]. The NiCK study has reported smaller brain volumes in transplanted patients, but no abnormalities in pre-dialysis patients aged 8–25 years. In this study, there was no association found with extent of eGFR loss, but transplanted patients had the most prominent loss of brain volumes as compared to conservatively treated patients with CKD. Separate comparisons of non-transplant and transplant CKD patients revealed only significant differences between the transplanted group and controls with respect to brain volumes. Unfortunately, no dialysis patients were included in this study [131]. In Belgium and the Netherlands, we performed a comparable study among 24 patients with CKD <30 aged 8–30 years (7 conservatively treated, 7 on dialysis, 10 transplanted for at least 2 years). We found smaller white matter volume and smaller volumes of subcortical structures (i.e., limbic system and basal ganglia) in all dialysis and transplanted patients, but not in conservatively treated patients. Dialysis and transplanted patients had equally smaller gray matter and subcortical volumes than healthy controls. Longer dialysis duration was predictive of smaller gray matter volume. DTI analysis indicated that dialysis and transplanted patients had lower white matter integrity in a widespread cluster of primarily distal white matter tracts compared to healthy controls [133]. The MRI findings were significantly associated with cognitive performance dysfunction (Lijdsman et al., in process). We found no difference in brain abnormalities between preemptively and non-preemptively transplanted patients, although the numbers were too low for a reliable comparison. We also found that a longer time post-transplantation during the patients' lifetime was related to worse white matter integrity. This could imply that CKD-induced brain abnormalities may not be reversible after a successful renal transplantation and may even worsen over time, potentially reflecting that CKD-induced brain damage become more pronounced while brain development continues (e.g., "growing into deficits") or it reflects delayed axonal degeneration (e.g., "Wallerian degeneration"). The fact that dialysis and transplanted patients – even preemptively transplanted – had comparable brain abnormalities suggests that not uremia itself, but rather microvascular damage or direct neurotoxicity by immune-suppressive maintenance therapy may play an important role in the pathophysiology of CKD-induced brain damage [134]. HTN and impaired cerebral perfusion is indeed another often mentioned potential determinant in CKD [135, 136]. This hypothesis fits with the specific localization of structural abnormalities revealed in the Dutch-Belgian study, as widespread disruption of white matter integrity has been previously been described in adult patients with HTN [137], which is a risk factor for cerebral perfusion. This speculation is in line with a recent review, concluding that CKD-related HTN may be a far more important risk factor for the influence of pediatric CKD on the brain than initially thought [135].

Impaired cognitive function may have a severe impact on the QOL of transplanted children and adolescents, as was shown in an Australian study on health-related QOL in adolescent kidney transplant recipients. Although overall scores were high, there were also important decrements in specific QOL domains, especially concerning emotion and cognitive dysfunctioning [120].

Late Outcome of Pediatric Transplantation

Data on long-term outcome of kidney transplantation should be interpreted in the context that they concern outcomes of patients that have (partly) been treated with currently outdated therapeutic regimens. A shortcoming of the existing data is that they are most often based on large and incomplete registry studies. Finally, the effects of long-term transplantation are to a certain extent often confounded by the carry-over effects of other types of kidney replacement therapy (KRT), i.e., hemodialysis or peritoneal dialysis, as the majority of patients have undergone different modes of KRT.

One of the few comprehensive cohort studies on late somatic and psychosocial outcome was a relatively small study on all 249 Dutch patients aged <15 years at onset of chronic renal replacement therapy between 1972 and 1992 and who were born before 1979, performed in 2000 and 2010, the so-called LERIC study. Thanks to the reliable registry system in the Netherlands, all patients who fitted the inclusion criteria could be traced. As nearly 80% of the time on KRT had been with a functioning graft in the late survivors, most outcomes reflect at least to a great deal the burden of transplantation. We will discuss outcomes in relation to other existing data on late outcome.

Late Graft Survival and Number of Transplants Over Time

Despite the potential increasing hazard of graft loss due to immunization, long-term follow-up data show that patients indeed can have multiple transplantations and that even the third or fourth transplantation in a patient can have a long survival. In the LERIC study, patients had changed their KRT modality between 1 and 11 times after a median KRT time of 25.5 years in 2010 [138]. The number of transplantations had been 1 in nearly 40%, 2 in 36.4%, 3 in 18.6%, 4 in 3.5%, 5 in 0.4%, and 6 in 1.3% of the 152 survivors by 2010 and after a median total KRT time of 25.5 years. Of all transplanted patients, 31% lived for more than 20 up to 37.2 consecutive years with a single graft. In some cases this was the third or fourth transplantation [139]. In 2000 and 2010, 75% and 79% of the surviving patients lived with a functioning graft. The ages of survivors in 2000 and 2010 ranged from 20–40 to 30–50 years, respectively. In a study on late outcome of 300 transplanted patients between 1973 and 2000 at Great Ormond Street Hospital in London, with a follow-up of 2.5–29 years, the median graft survival was 10.8 years (95% CI 6.9–14.6) and 46% and 37.9% after 15 and 20 years [140].

Late Overall and Cardiovascular Mortality

Both ANZDATA and LERIC studies on long-term survival in patients aged <20 years with KRT onset 1962–1992 found a 30 times increased mortality after a mean of 15 and 12 years of KRT time, respectively [141, 142]. The Great Ormond late outcome study on transplanted children with a median follow-up of nearly 20 years mentioned 37 deaths on 300 transplanted patients, a significant lower figure, reflecting the relative favorite situation of transplantation over dialysis with respect to survival [140]. Cardiovascular disease was most often reported as cause of death in both Australian and Dutch studies and in a German long-term follow-up study (41%, 43%, and 50% of cases, respectively [141, 142], but also in the Great Ormond transplantation long-term outcome study (32%) [140]. A long-time burden of HTN, onset of KRT at <6 years of age, onset of KRT before 1982 and, most important, the cumulative dialysis duration were significantly associated with premature death in the LERIC study [141]. Ten years follow-up of the LERIC study (25 years of mean KRT time) showed a significant trend from cardiovascular disease to infections and malignancies over time as the most important cause of death, reflecting the increasing impact of transplantation over time. However, an increased awareness over time among physicians of CVD as important threat and an overall change in lifestyle might also have influenced the reduced prevalence of CVD-related death. In 2000, uncontrolled HTN had been highly prevalent among the transplanted survivors, whereas in 2010, survivors had on significant lower BP, used more antihypertensive drugs – especially more ACE-inhibitors – had had more often cholesterol lowering medication and less often left ventricular hypertrophy on cardiac ultrasound [138].

The late outcome data may overestimate the mortality risk of the current pediatric KRT population, as preemptively transplantation has become the first choice of therapy in countries which has reduced the total time on dialysis in pediatric onset ESKD patients over time. Registry data show indeed improved outcomes of childhood ESKD over 40 years of KRT, but at the same time a dramatic slowdown of this improvement over the last 25 years [141–145]. The ANZDATA, LERIC, and a Canadian long-term outcome study reported no increase in survival after 1983 or 1992 (Canada), respectively [138, 142, 143]. In line with this, the adjusted 10 years survival rates of patients with onset of KRT at age 0–21 years according to the USRDS in 1996 and 2003 were equal (71.3% and 71.8%, respectively) [145]. This development may be partly due to the fact currently more infants and disabled patients are accepted for KRT than in the 1980s and 1990s of the last century, but the fact remains that the mortality rate has remained unacceptably high. Other studies have confirmed the impact of CVD on premature death in patients with childhood-onset KRT [1, 139, 142–144, 146].

Both the ANZDATA and Canadian Registry studies show similar results with respect to dialysis and young age as risk factors, but in both studies the increase in mortality risk due to dialysis only became significant in patients with a dialysis vintage >2 years [142, 143].

Other Comorbidity

In 2000, >40% of survivors in the LERIC study (median age 30 years), 75% of them with a functioning graft, suffered from comorbidities that affected their activities of daily life. This concerned chronic fatigue, symptoms related to CVD (shortness of breath, recurrent angina), symptoms related to peripheral neuropathy, or disabilities due to locomotor disorders [147–150]. In 2010, more patients reported more often chronic fatigue as important, affecting daily life and negatively impacting the ability to participate in the labor market [151].

Cardiovascular Disease

In 2000 we assessed in 140 of 187 surviving patients for surrogate markers for CVD. Nearly 50% of all living male and 40% of all female LERIC patients were found to have moderate to severe left ventricular hypertrophy (LVH), 75% of them being transplanted for >2 years at the time of the investigation [148]. Arterial wall stiffening was significantly more prevalent in all patients than in age-matched peers [149]. In contrast, between 2000 and 2010 only 1 patient out of 34 died of CVD [138]. Among the survivors, the prevalence of cardiovascular risk factors decreased from 41.3% in 2000 to 18.8% in 2010. The odds ratios (Ors) in 2010 relative to 2000 for LVH, HTN, and hypercholesterolemia were 0.26, 0.22, and 0.04, respectively. ACEi and cholesterol-lowering medications were prescribed significantly more often in the period 2000–2010 than in previous years (OR 7.4 and 11.5, respectively) [152].

These outcomes reflect the burden of CVD in young patients with pediatric ESKD, but also the reversibility of CVD during the years of transplantation, provided strict and effective cardioprotective management is followed. Studies on CVD in children with ESKD confirm that LVH may occur early in life, is strongly associated with HTN, and may be reversible after transplantation as long as HTN is well controlled [4, 153]. This underscores the importance of BP control in both young transplanted and dialyzed patients. There still seems much to be learnt in this area, as relatively recent data of the European Society for Pediatric Nephrology/European Renal Association–European Dialysis and Transplant Association registry and North American Pediatric Renal Trials and Collaborative Studies mention 40–65% of children on KRT with uncontrolled HTN [4, 5, 154, 155]. A Belgian-Dutch study from 2016 in transplanted patients 8–30 years of age showed a more favorable picture during childhood, but also a sharply increased percentage of uncontrolled HTN in the age group 25–30 years [8].

Infections

In the LERIC population, infection has become the most important life-threatening comorbidity over time [138]. Between 2000 and 2010, 44% of 34 casualties died of infections. The contribution of infection to hospitalization increased significantly during the last decade in transplanted patients, with an increase in the hospital admission incidence rate ratio for infections over other causes from 0.25 to 1.0. The admission rate for urinary tract infections (UTIs) also significantly increased over decades in transplanted patients [156].

In adults, infections are the leading cause of death in the first year after kidney transplantation [157]. UTI (69.8%) and CMV infection are most frequent during the first 6 months, but UTI is also highly prevalent much later after transplantation. In a retrospective cohort study on 28,942 Medicare renal transplant recipients, the cumulative incidence of UTI was 60% for women and 47% for men at 3 years after transplantation. Late UTI was significantly associated with an increased risk of subsequent death [adjusted hazard ratio IAHR) 2.93] and graft loss (AHR 1.85) [158].

Data from adult studies suggest a relationship between an increase in the intensity of immunosuppressive maintenance therapy and an increasing incidence of serious infections. This association seems related to the increase in dose rather than to the use of a different type of potentially stronger immunosuppression [159, 160]. LERIC patients have in general been treated with relatively mild immunosuppressive regimens when compared with most current strategies in transplanted children. This makes the findings in the LERIC patients particularly alarming for the current group of young transplant recipients. Lowering the immunosuppressive load, especially in patients with a prolonged rejection-free period after transplantation, might reduce the number of fatal infections.

Malignancies

Based on several reports on malignancies after pediatric solid organ transplantation, the cumulative incidence of cancer seems to increase from 7%, by 10 years to 13–15% by 20 years and 26–41% by 30 years post-transplantation [32]. The incidence varies among studies due to differences in patient characteristics, type of transplantation, geographical (UV) influence, and cancer screening practices. The long-term risk of cancer among pediatric solid organ transplantation is 12–33 times greater than the general population [32]. In 2010, 54 (21%) LERIC patients of the Dutch cohort study had developed 105 de novo malignancies after a median KRT time of 25.5 years. The incidence rate and incidence rate ratio for cancer was 2.0 and 21.7, respectively, for all patients and 26.0 and 81.5, respectively, for patients 45–50 years of age. The cancer-free survival after 20, 30, and 35 years of follow-up was 87%, 68%, and 58%, respectively. Of all transplanted patients, 30% had died without malignancy, 33% had at least one malignancy, and only 36% was alive without malignancy in 2010. A cumulative incidence competing risk analysis showed that after 30 years of transplantation of all survivors, 41% had developed cancer and 31% had a second de novo cancer within 1 year after the initial cancer diagnosis. The median age at malignancy diagnosis was 33.5 years (range 11.0–49.0) and the median KRT time was 25.0 years. Death was attributed to a malignancy in 13 (24%) patients [161, 162].

Skin cancer was by far the most common type of cancer in the LERIC study, even more pronounced than in other studies [161–164]. The adjusted risk for non-melanoma skin cancer (NMSC) was increased >200 times and the majority occurred at a later age than previously reported, i.e., 39.1 years (range 21.8–50.4). Including metastases, 114 NMSCs [78 squamous cell carcinoma (SCC) and 36 basal cell carcinoma (BCC)] occurred in 39 patients. The overall incidence rate ratio for SCC was 744 and for patients 45–50 years of age it was 2610. Two patients died of SCC; far more patients had important morbidity because of SCC metastases. There were five melanomas occurring at a median age of 31.1 years, seven episodes of post-transplant lymphoproliferative disease (PTLD) occurred in six patients at 0.6–20.8 years after the first transplantation and nine solid non-skin/non-lymphoproliferative tumors, all of different origin, at a mean age of 41.7 years, consistent with a rate of 158/100,000 patient-years [162].

Other pediatric ESKD studies have found a lower malignancy incidence than that in the 2010 LERIC extension, but in line with the LERIC data of 2000, which reflects the relatively late onset of cancer after transplantation [146, 165–167]. The predominance of SCC over BCC seems to be more pronounced in pediatric than in adult transplant recipients (2.8:1 versus 1.7:1) [163]. SCC is primarily found in parts of the body that are exposed to sunlight, may develop rapidly, and recurrences are common [168] (Fig. 1).There is evidence that ultraviolet light exposure and human papilloma virus (HPV) in combination with immunosuppression – especially azathioprine – are potential causative factors for SCC [169, 170]. Switching from tacrolimus or cyclosporine to sirolimus has been shown to be preventive against the development of new SCC among kidney-transplant recipients with previous SSCs [171]. SCC may appear in the absence of any preexisting skin lesion, but is often preceded by actinic keratosis, which suggests HPV involvement in its pathogenesis (Fig. 2). A recent study showed in a skin cancer model how musculus papillomavirus 1 infection caused cSCC in cyclosporine-treated mice, even in the absence of UV light [172]. Recently, it has also been shown that in a mice study how vaccination against HPV may protect against skin cancer development. In this study, mice with natural or acquired immunity against mouse papillomavirus type 1 (MmuPV1) were protected against skin carcinogenesis induced by ultraviolet radiation or chemicals in a manner dependent on CD8+ T cells [173]. Lastly, it has been shown that polygenic risk scores (PRSs) calculated from genome-wide association studies of NMSC in a general, non-transplant setting, also predict risk of and time to post-renal transplant skin cancer [174].

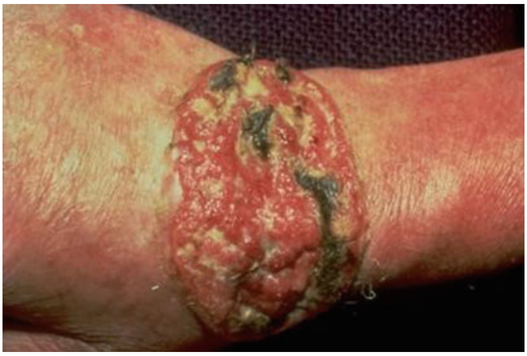

Fig. 1 A 42-year-old man with recurrent squamous cell carcinoma 31 years after pediatric kidney transplantation (with permission from patient)

Both LERIC and the Israel Penn Transplant Tumor Registry Study data show an earlier onset of melanoma compared with NMSC [162, 163]. Melanocytic nevi, a risk factor for melanoma, may develop in excess after transplantation [175]. In transplantation, melanoma can be transmitted by the donor. Persons with a history of melanoma should be excluded from donation. Sun protection and removal of suspect nevi are the most important protective measures.

PTLD has biphasic onset with a first peak at 6–12 months and a second 5–10 years after transplantation. Early-onset PTLD is associated with active EBV infection in 95% of patients and has a better prognosis than the late-onset form [33, 176]. The incidence of PTLD increased up to the early 2000s, but more recent United Network for Organ Sharing data have shown a downward trend among adult kidney recipients who were transplanted between 2007 and 2009 as compared to those transplanted between 2000 and 2003, all due to a decrease in EBV-associated PTLD [176]. Early detection of EBV activation by polymerase chain reaction and subsequent adjustment of immunosuppression may have positively influenced this trend.

Renal cell carcinoma is the most common solid non-skin carcinoma after transplantation and often affects the native kidneys. The fact that the incidence is higher than in HIV patients may indicate involvement of local renal factors, more than immune suppression as risk factor [177].

Bone Disease and Motor Disabilities

Over two-third of the LERIC population was severely growth retarded (height <−2.5 SD), as expected in patients from the "pre-growth hormone era." More than one-third daily suffered from bone pain or had disabilities related to metabolic bone disease. About 18% were severely disabled because of bone disease [147]. Uncontrolled chronic kidney disease-mineral and bone disorders (CKD-MBD) during growth in addition to transplantation-associated factors, such as glucocorticoid-induced suppression of bone formation, calcineurin inhibitors

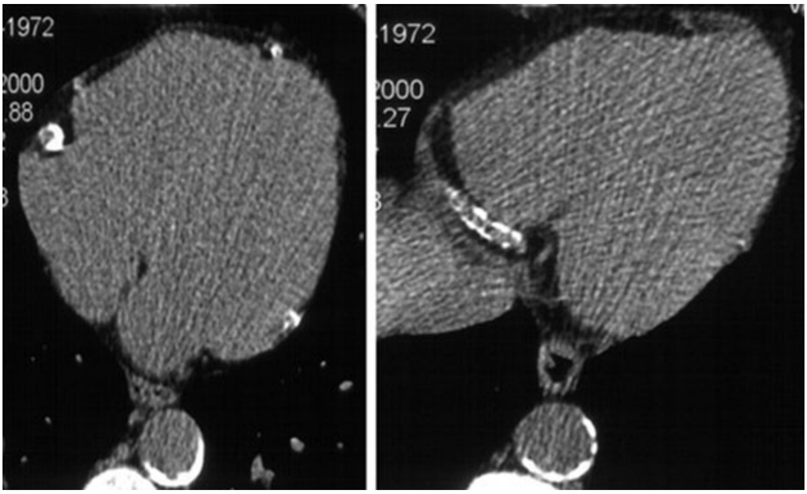

Fig. 2 CT sections from a 27-year-old male on hemodialysis with childhood-onset of ESKD showing extensive calcification in all three coronary arteries and aorta. (From Oh et al. [139])

(CNIs) and persistent hyperparathyroidism may all have added to this situation [147, 167]. The use of bisphosphonates has been shown to improve bone mineral density in transplanted patients, but the positive effect on fracture risk and clinical improvement of BMD has still to be demonstrated [178].

Cognitive Functioning

In 2000, we found intelligence quotient (IQ) scores among the LERIC patients to be on average 10 points lower than in the age-matched Dutch population, in line with studies on IQ performed in CKD children [125, 179]. The most important determinant of impaired schooling and cognition was a relatively long period of dialysis during youth, but we found no differences in intellectual performance between patients on dialysis or transplanted patients at time of assessment. Most deficits were found in tasks requiring concentration, memory, and general knowledge [125]. These deficits are reflected in cognitive impairment in adult hood [125, 180]. Data on the reversibility of cognitive impairment after transplantation are conflicting, and may be different in children than in adults [133, 181–183].

Quality of Life

Both mental and physical health-related QOL scores of transplanted LERIC patients were similar to those of the age-related general Dutch population in 2000, but physical scores were significantly more often impaired in 2010 than in 2000 [184, 185]. Although partly explained by a normal aging effect, the LERIC transplanted patients appeared to be “early agers” in this respect, and the ongoing deterioration, over and above relatively low scores in some domains, could become a significant problem for these patients in the near future. A transplanted woman, age 42 years, illustrated this through the following comments: “Much more often than 10 years ago, even when I was on dialysis, I feel very tired nowadays, reason why I recently have decided to stop working for a while.” According to the same study, all domains relating to psychosocial functioning had remained stable over the last 10 years [185]. Being employed was associated with a lower risk of impaired QOL in the domains of physical functioning, vitality, and general health perception for all LERIC patients. Having offspring was associated with less impaired social functioning and a relatively high income was associated with fewer role limitations due to physical problems [184, 185].

All, except one Japanese study, emphasizes the improvement in QOL after renal transplantation in young recipients, but these favorable outcomes are reported after at most 10–20 years of follow-up [186–188]. The high mental QOL scores of dialysis LERIC patients sharply contrast with the very poor mental scores found in age-matched dialysis patients with adult-onset ESRD in the Dutch NECOSAD-2 study [184, 189], but are consistent with findings in other QOL studies in adults with chronic childhood diseases, such as sickle cell disease and cystic fibrosis [190]. Different coping strategies and expectations of life and different coping strategies between children and adults may explain this difference in mental status. It fits with the hypothesis that health-related QOL is, to a large extent, based on the difference between health expectations and health experiences. Nearly 80% of the LERIC patients stated that their disease had brought them something positive in life. The perceived benefits of having ESKD included more satisfaction with (small things in) life, having developed a sense of perseverance, and positive responses from friends and relatives [185].

Social Outcomes

Employment. In 2000, 67.4% of the LERIC patients were employed [191]. Involuntary unemployment was reported in 19.1% versus 6.4% in the Dutch population of similar age. Most patients (53%) had low-skilled and only 10% had high-skilled professions, a situation significantly different from the average Dutch population. In 2010, 61.8% were still employed; of these patients, 81.8% had at least 50% full-time equivalent of paid work [151]. Having motor disabilities, chronic fatigue, and being on dialysis were the most important factors for becoming unemployed. Some patients reported that their contract was not renewed as a direct result of disclosure of their dialysis patient status to their employer. Unemployment was related to patients' low subjective health perception independent of the objective physical condition or KRT mode. Between 2000 and 2010, we found a significant trend toward more highly educated occupations and an increase in patients' educational level. The average income, however, was significantly lower compared with the general population in 2010 (no data in 2000); 35.2% of patients had lost their job between 2000 and 2010, in 32.3% because they were fired and in 45.2% for medical reasons. In 12.1%, employers indicated that the disease state of the patient influenced achievement. About 21% of patients felt that their disease had a significant negative influence on their professional achievements and career [151].

Other data confirm the LERIC findings [167, 180, 182, 185, 188, 192]. In a recent French study in 624 patients transplanted in childhood, fewer patients than expected had a high-level degree, more patients were unemployed and mean incomes were much lower than in French society [180]. Interestingly, patients less often had a permanent contract than the average French employee (66.8% versus 81.8%). This might reflect the observed reluctance of employers to a long-term professional commitment with renal patients, as we observed in the LERIC study. Nearly 50% of French transplanted patients indicated they had suffered from discrimination [180].

Partnership and autonomy. In line with the French study, in 2000 we found sequelae of impaired autonomy in the LERIC cohort [180, 191]. Of the 144 patients, 49 (34%) still lived with their parents. The odds of living with parents versus living alone for LERIC patients compared with age-matched Dutch citizens was 3.3 [95% confidence interval (CI) 2.3–4.7], while the odds for living with a partner was 0.3 (95% CI 0.2–0.4) for LERIC patients compared with age-matched Dutch inhabitants. In 2010, the situation in the LERIC cohort had completely changed: 67.4% were married or lived with a partner and 28 (31.5%) had offspring, compared with, respectively, 74.4% ($P > 0.05$) and 64.8% ($P < 0.05$) in the general population [151]. This delay in starting a relationship could reflect a genuine delay in sexual maturity or a late "social maturity" as has been described in patients with a chronic illness. Patients with disabilities and patients from southern more often than from northern European countries tend to live with their parents. Men more often have problems with finding a life partner than women [151, 180, 182, 188, 192].

Abstract

A diagnosis of kidney disease impacts a child, their family, and potentially their community. While sometimes acute, kidney disease is often chronic with lasting effects and requiring significant treatments. The complexity and chronicity of pediatric kidney disease raises ethical challenges for pediatric nephrologists, children, and their families. In this chapter, we will provide an overview of the principles of biomedical ethics and the best interest standard and harm principle in medical decision-making for children with kidney disease. We will highlight the unique

Introduction

To consider the ethical issues in pediatric nephrology, it is important to begin with the common framework used in contemporary discussion of medical ethics. Children pose a unique challenge to ethical frameworks initially developed around the experience of an autonomous adult patient. While the predominant framework presumes that the patient is fully autonomous and able to express authentic and sustained values to help guide decisions, these capabilities are generally not attributed to children. Additionally, nearly all pediatric patients are cared for within the context of a family. Parents carry responsibilities for the well-being of their child not shared by family members of an autonomous adult patient. Furthermore, society and, in turn, pediatric nephrologists have additional responsibilities for children. It is important to recognize these distinct aspects of children when considering the ethical issues in pediatric nephrology.

Within this chapter, we will briefly review principlism, the most commonly applied framework in medical ethics [1, 2]. Next, we will review the best interest standard and harm principle in surrogate medical decision-making for children with kidney disease. We will highlight the unique ethical issues that arise among the youngest patients and adolescents nearing adulthood. Finally, we will consider issues of justice within practice of pediatric nephrology.

Overview of Principlism

Medical ethics arose from a rich foundation, incorporating the professional ethics of physicians and other health practitioners throughout history as well the insights of both Western religious and secular ethical traditions. Principlism reflects efforts to identify the common values, or “principles,” which were found in these heterogenous sources. In *Principles of Biomedical Ethics* [2], Beauchamp and Childress identified four common, overarching principles represented in the vast majority of medical ethics: respect for autonomy, beneficence, nonmaleficence, and justice (Table 1). Medical care should adhere to these principles to the greatest extent possible.

Principlism holds each principle is of equal value and importance. Difficult questions in medical ethics typically arise when these principles conflict with each other. We will examine the complex aspects of applying these ethical principles within pediatric nephrology in the remainder of the chapter.

Pediatric Surrogate Decision-Making: The Interface of the Principles of Respect for Autonomy, Beneficence, and Nonmaleficence

By their very nature, children are in an earlier stage of cognitive development than autonomous adults. It is generally presumed that pediatric patients lack the ability to make autonomous decisions. In contrast, adult patients are presumed to have the ability to make autonomous decisions absent evidence otherwise. As children are not considered fully autonomous, medical decision-making for a child is made by a surrogate, usually a parent. Parents serve as surrogate decision-makers due to a combination of factors: their intimate knowledge of their child’s developing worldview, a presumption that they have a stronger interest in their child’s well-being than the public-at-large, the fact that they play an integral role in the logistics of providing care for a child, and a strong cultural and legal tradition of deference to parental authority.

Parental surrogate decision-making is inherently different than surrogate decision-making for a previously autonomous adult. Surrogate decision-makers for a previously autonomous adult, guided by an advance directive or substituted judgment, are asked to make a decision as the patient would have had they remained

Table 1 The four principles of biomedical ethics [2]

Principle	Brief description
Respect for autonomy	Health practitioners should provide care consistent with the goals and values of the patient receiving care. This should be guided by the decisions of the informed and competent patient whenever possible
Beneficence	Health practitioners should seek to provide care that would be expected to do the most good for their patients
Nonmaleficence	Health practitioners should seek to avoid care that would be expected to harm their patients
Justice	Health practitioners should seek to ensure that only clinically and ethically relevant facts are used as the basis for medical decision-making. Within the broader health care system, the principle of justice suggests that the burdens and benefits of medical care be fairly distributed

autonomous out of respect for the patient's previous autonomy [3]. In contrast, children have never been autonomous; thus, substituted judgment cannot be employed by parents. Instead, parents and healthcare providers are tasked with considering the best interests of the child [4]. Parental authority as surrogate decision-maker is not absolute and may be constrained in some instances where the parental choice would result in harm to the child.

Best Interest Standard

The best interest standard directs decision-makers to focus purely on the child's good, considering the present and future self-regarding interests of the child alone, and make the choice that maximizes benefit (i.e., principle of beneficence) and limits harm (i.e., principle of nonmaleficence) to the child [2–4]. For example, treatment of a relapse with efficacious systemic steroids is likely in the best interest of a child with steroid-sensitive nephrotic syndrome. Treatment with systemic steroids offers the present and future benefits of attaining remission and decreases risk of harms such as peritonitis, thromboembolism, or volume overload. Although systemic steroids are not without potential harm, when balanced against the potential benefit they may provide, it is likely that treatment with systemic steroids is in the child's best interest rather than an alternative choice such as a steroid-sparing agent or no therapy at all. As a result, pediatric nephrologists should guide parents to select systemic steroids, and parents should do so. In other circumstances, systemic steroids may not be in the best interest of the child with nephrotic syndrome. For example, were the child to have more frequent relapses, less or no response to, or greater side effects from systemic steroids, further systemic steroids may not be in a child's best interest as they would not maximize benefit and minimize harms to the child, and a different approach may be warranted.

Although the best interest standard has been long established within medical decision-making and legal contexts, it is subject to certain criticisms. Parents face competing obligations, which may preclude making decisions with a single child in mind [5]. Parents may have other children, a partner, other family members, friends, employers, and others to whom they owe obligations in addition to obligations to their own health and well-being [6]. Furthermore, while the best interest standard is often helpful, it offers limited guidance when the choice of what is "best" is unclear. This may be more common in complex, chronic diseases such as advanced chronic kidney disease where the disease is chronic, incurable, expected morbidity may be significant, costs and other burdens placed on others may be high, and societal resources are limited [7]. Due to these limitations, while the best interest standard works well to guide decision-makers, it does not function well as a threshold for pediatric nephrologists to seek state or institutional power to override a parental decision [8].

The Harm Principle

Parents may place different values on benefits and burdens of treatment options compared to medical professionals. This means well-meaning parents and pediatric nephrologists could arrive at different interpretations of what is “best” for a child. Rather than guiding parents and clinicians toward making the best decision, the harm principle seeks to define what choices should be considered unacceptable for parents to make, thereby justifying seeking institutional or state power to override those choices [9]. Parents are not required to make the very “best” decision for their child in all situations. Instead, they should not be permitted to make decisions (usually a refusal of treatment) in which serious, imminent harm is expected to occur to the child, an alternative could avoid that harm, there are no reasonable alternatives to overriding the parents, and there would be broad social agreement with providing the recommended therapy in this and other similar situations [9–11].

Seeking State Intervention

Wherever possible, clinicians should seek to work with patients and their families even in the setting of disagreement over treatment choice. This can involve repeated meetings, providing additional education, seeking support from a multidisciplinary team, pursuing mediation, and other pursuits. In rare circumstances, these approaches may fail, resulting in an intractable conflict. In cases where nephrologists feel a parent’s choice for their child should not be respected, state intervention should be sought to overrule parental authority and provide consent for treatment on behalf of the child. As a general rule, nephrologists should seek state intervention only as a last resort, as court involvement to order treatment over parental objections represents a serious challenge to parental authority and may permanently alter a family’s future interactions with medical providers.

The exact process of seeking state intervention varies between countries and regions. This is impacted by at least three factors. First, legal precedent justifying state intervention differs between countries. For example, in the United States, state intervention is justified when a parent refusal meets a threshold of harm (exceeding the harm principle) [9, 12]. In contrast, in England state intervention is justified if a judge believes a parent’s decision is not in the child’s best interests [12]. This means in certain circumstances, state intervention may be appropriate in England (choice not in child’s best interest), but not in the United States (choice exceeds harm principle) [12]. Second, the availability of resources varies significantly between countries. For example, in low- and middle-income countries standards justifying state intervention may be based upon the best interest of the child or harm; however, in practice they are not enforced as there may be insufficient resources to pay for efficacious treatment that is in the best interest of the child [13–15]. Third, the harm principle requires public consensus (test of publicity) that overruling parental refusal is justified [9]. This means it is possible state intervention may be justified in one country, but not in another based on variation in public consensus between countries and regions.

Recognizing the complexity of nephrologists seeking state intervention to overrule parental authority, there remain cases in high-income countries where it is clearly indicated. For example, parental refusal of recommended dialysis for a 6-year-old with stage 3 acute kidney injury from diarrhea associated hemolytic uremic syndrome, clear indications for acute dialysis, and a high likelihood of renal recovery, and no known comorbidities may violate the harm principle. Refusal of dialysis treatment places the child at clear risk for severe, imminent, and preventable harm compared to the alternative (dialysis). If a parent refused dialysis in this situation, a pediatric nephrologist could apply the harm principle and explore whether the parent’s choice can be respected or whether their authority should be abrogated and consent for treatment be provided by the state. Similarly, a nephrologist should seek state intervention to overrule parental refusal of all treatment for grade IB acute cellular-mediated rejection of kidney allograft for their child. Refusal of treatment places the child at clear risk for serious, preventable, and imminent harms (e.g., loss of kidney allograft) compared to the alternative (immunosuppressive medications). The risks of immunosuppressive medications do not exceed those of no treatment. There is not a less intrusive alternative to seeking to overrule parental refusal, and such a decision could be generalized to similar cases, and most parents would agree intervention is reasonable. Additional examples that likely exceed the harm principle threshold for seeking state intervention include parental refusal of immunosuppression for a child with active class IV lupus nephritis, refusal of all therapy for a child with idiopathic nephrotic syndrome, and refusal of antibiotics for spontaneous bacterial peritonitis for a child with nephrotic syndrome. In contrast, parent refusal of antihypertensive medication due to a preference to focus on lifestyle modifications for a child with longstanding stage 1 hypertension may not be in the child's best interest but is unlikely to exceed the threshold of the harm principle. Parental refusal may place the child at risk for development of cardiovascular or kidney disease, but the significance and imminence of this risk is less clear. Additionally, the parent's preferred treatment of lifestyle modifications could also decrease those risks, albeit less so than with additional medications. Finally, it is unlikely that state intervention could be generalized to similar situations or that most parents would agree that state intervention was reasonable. In each case, a decision to seek state intervention to overrule parental authority requires due consideration and deliberation, and likely the involvement of a multidisciplinary care team potentially including social work, ethics consultant, and others [16].

Decision-Making in Special Populations in Pediatric Nephrology

Infants

Historically, initial attempts at neonatal and infant dialysis were associated with poor outcomes, mortality, and morbidity. As a result, a consensus emerged within the pediatric nephrology community that there was no moral obligation to provide dialysis treatment to infants if parents did not want to pursue such treatment [17–19]. Due to improvement in knowledge and technology over the last 40 years, outcomes have markedly improved. An analysis of the North American Pediatric Renal Trials and Collaborative Studies cohort (NAPRTCs) between 2000 and 2012 demonstrated a long-term survival rate of 78.6% among newborns for whom dialysis was initiated at less than 1 month of age [20]. Similar findings have been reported across a wide variety of studies [10]. Yet, while international surveys of the medical community suggest that the vast majority of pediatric nephrologists will offer dialysis to at least some infants with end stage kidney disease, the surveys also demonstrate that a majority of nephrologists feel it remains permissible for parents to decline such therapy for infants less than 1 year of age [21–23].

Application of the ethical frameworks discussed earlier in this chapter highlight two aspects of the decision-making process for these infants that require scrutiny. First, should the improvement in the outcomes for infants treated with kidney replacement therapy constrain the range of treatment choices for parents when examined through the lens of either the best interest standard or the harm principle? [10, 19, 23, 24] Second, it is important to recognize that medical professionals are more comfortable withholding life-sustaining treatments in neonates than in older infants and children [25]. An informal survey of members of the European Peritoneal Dialysis Working Group demonstrated this phenomenon, in which 55% of respondents felt that it was acceptable to respect a parent's wish to refuse dialysis for an otherwise normal neonate (<30 days of age), whereas only 26% felt parental refusal was acceptable for an infant 1–12 months of age [23]. These results suggest pediatric nephrologists and other clinicians consider neonates as a distinct group from older infants [25]. Yet, is such a distinction ethically warranted? As discussed above, a central aspect of the principle of justice is that only clinically and ethically relevant aspects of a patient should be considered when determining whether or not to provide a given treatment. It is not clear that this distinction in decision-making between newborns and older infants would qualify. Further details on the ethics of infant dialysis are discussed in ▶ Chap. 77, "Infant Dialysis."

Adolescents

While most children are presumed to lack the capacity to make autonomous decisions, this capability develops throughout childhood. Adolescence marks a period of transition from childhood to adulthood characterized in part by developing the capacity for autonomy. This process varies significantly from patient to patient, likely continues into the patient's 20s, and is further complicated as there is not a singular aspect of cognitive or emotional development that clearly corresponds to "adulthood" or the ability to make "autonomous" decisions [26].

While different countries may recognize adulthood at different ages in various cultural and legal contexts, all pediatric nephrologists face a dilemma of balancing respect for an adolescent's developing autonomy, parental authority, and acting in the adolescent's best interest [27–29]. As patients mature, it is appropriate to seek out and become more deferential to their values and goals, and to incorporate them into shared decision-making. This is supported by two ethically relevant considerations: (1) Respect for autonomy can encompass respect for the developing autonomy of an adolescent. (2) The adolescent's goals and values should help shape assessments of beneficence and nonmaleficence for the patient. This approach is codified in some countries. For example, in England, adolescents aged 16–17 are assumed to have competence to provide consent for medical treatment independent of parental consent [30]. Additionally, certain adolescents under age 16 may provide consent if they are found to demonstrate Gillick competence [30]. This requires demonstrating sufficient maturity and intelligence to understand and appraise the nature and implications of the proposed treatment, including the risks and alternative courses of actions. Importantly, Gillick competence permits an adolescent to provide consent for medical treatment without parental consent but does not permit any adolescent (less than 18 years) to refuse a treatment that is in their best interest [30]. In this way, a "Gillick competent" adolescent could provide consent to receive treatment such as antibiotics for spontaneous bacterial peritonitis but could not refuse it as the treatment is clearly in the adolescent's best interests.

In some circumstances, an adolescent patient may refuse a recommended treatment that, in the eyes of the clinician, is clearly the most beneficial course of action. While a strict ethical analysis of a given circumstance might support treating a pediatric patient over their objections, this is practically challenging, if not impossible, if an adolescent with kidney disease actively dissents [28]. This may be particularly true for treatments that are chronic or those that require some level of patient participation such as dialysis or maintenance of kidney transplant [28]. Forcing an adolescent to receive treatment over their own objection risks obliterating all therapeutic alliances and trust between patient and care team, and the harms of such an approach likely will outweigh the benefits. Instead, pediatric nephrologists should pursue a more comprehensive, multidisciplinary approach. This should include continued engagement with the adolescent and their family to better understand their concerns. It is possible that clinicians' perception and grading of benefit and burden of an intervention may be very different than that of the patient themselves [28]. Additionally, pediatric nephrologists should solicit input from allied professions such as social work, psychology, palliative care, ethics, religious counsel, or others in an effort to reach consensus on the course of action moving forward.

Considerations of Justice

Justice is a complex principle concerned with fair, equitable, and appropriate treatment in light of what is owed to persons [2]. The minimal requirements of justice in western bioethics are reflected in Aristotle's principle of formal justice which holds that equals must be treated equally and unequals must be treated unequally [2]. As applied to children with kidney disease, it means that two children with the same kidney disease should be treated similarly unless there is a morally significant difference between them. Although intuitively appealing, this interpretation of justice is challenged by realities encountered by pediatric nephrologists including expensive treatments, impact on caregivers and families, and systemic injustices among others. These challenges impact individual patient encounters, work with communities and within a healthcare system, and the role of nephrologists as global citizens.

Justice and Resource Constraints

Medical care has a cost which must be paid for it to continue to be available [31–33]. While experienced differently depending on healthcare system and socioeconomic status, nearly all patients and their families must contend with the cost of medical treatments. One area where high costs are experienced is expensive drug treatments. Most treatments for children with kidney disease require the prescription of increasingly expensive medications. Inability to pay for such treatments increases the risk of poor outcomes such as the progression of chronic disease and transplant graft failure [34, 35]. Among the most expensive medications are new biologic agents which offer the possibility to control, but not cure, conditions and require a lifetime of administration [36]. The most expensive of these cost several times the per capita gross domestic product of even the most affluent nations [33, 36]. Even acknowledging the considerable costs of drug development and the role of collective resources such as group health insurance or nationalized health care to spread the costs of a treatment over a population, such a model of expensive treatment is not sustainable on a large scale [35, 36]. The UN Universal Declaration of Human Rights classifies medical care as a basic necessity [37]. If medical care is a basic necessity, excessively high drug prices are unjust because they exploit the vulnerability of the patient and their family [33].

Recommending, requesting, or requiring treatment without a mechanism to pay for it is an additional stress on decision-making and raises ethical concerns of fairness. Disease and the expense of treating it are not distributed equally, nor are children generally viewed as being responsible for their state of health. As a consequence, fairness may dictate societal support to mitigate the expense of medical care for children. Recognition of this tension suggests pediatric nephrologists should be conscious of the expense of treatments and openly discuss this with families, seek to improve access to preventative and cost-efficient treatments, and work with allied professions, patients, and families to advocate and demand for resources for particular patients and more generally for implementation of public health policies to support children with kidney disease and their families [36, 38].

An example of the efficacy of such advocacy was the efforts nephrologists and others to highlight the limited access to dialysis treatments in the United States in the 1960s and 1970s driven by cost. Public outrage at the subsequent rationing of dialysis treatment led to incorporation of the provision of dialysis treatment within the Medicare entitlement in the United States. In effect, end stage kidney disease became the only disease for which there is nationalized healthcare available for American citizens. While a useful example, advocacy alone cannot address the significant expense of treatments for pediatric kidney disease experienced throughout the world, particularly in lower- and middle-income countries where resources to treat disease are more constrained.

Denial of access to medical treatment based on ability to pay raises serious concerns of justice, even if practically they may be unavoidable. One approach advocated in these circumstances is to utilize the principles of procedural justice to develop clear, explicit procedures for considering decision-making for every child [15, 39–41]. Specifically, a fair process requires that four conditions be met: publicity, relevance, revision and appeal, and regulation [41]. When established, procedures for allocating scarce medical goods must be specific to a country or broader region to account for varying levels of available resources and social supports. These procedures should include stakeholders (patients, caregivers, nephrologists, and community leaders) in their development, be informed by relevant evidence and ethical principles, and offer the opportunity for patients and caregivers to appeal a decision.

Examples of such policy are the explicit systems of kidney allograft allocation developed by many individual countries and groups of countries. These systems define the criteria by which kidneys are allocated (waiting time, age, severity of illness, etc.), are publicly available, and strictly allocate kidneys by these criteria. While such frameworks cannot guarantee all children receive a desired treatment, they offer each child and their family a fair and open process for decision-making.

Caregiver Burden

Pediatric chronic kidney disease impacts not only a child, but also their family and community. In a systematic review of studies of caregiver experience in pediatric CKD, Tong and colleagues described the experience as “pervasive and profoundly negative experience” [42] . Going further, Ojo described development of ESKD as “a life-changing tragedy for the child, their family, and their community” [43]. These descriptions reflect the significance and import of the burdens placed on caregivers of children with CKD, particularly mothers. Caregiver burden is best thought of as a multidimensional construct reflecting an individual’s perception of overload during the caregiving process in one or more of four perspectives: physical, psychological, social, and financial [44]. While caregiver burdens may be greatest for younger children and those with more advanced kidney disease, these impacts may be experienced caring for children in all levels of CKD [7, 45–51]. At its most significant, caregivers (particularly mothers) experience extraordinary burdens which, in some circumstances, exceed their available physical, financial, or psychological resources, so they are unable to meet their duties to themselves or to others for whom they are responsible [6, 7, 45, 46]. This experience has been reported by caregivers throughout the world and is influenced by the available social resources within each country [7].

In light of the severity of the burdens experienced by at least some caregivers, it seems cruel and unjust for nephrologists not to discuss expected burdens with parents. This raises challenging ethical questions including how clinicians and parents could or should incorporate considerations of caregiver burden into medical decision-making for a child with chronic kidney disease. More directly, these cases highlight a situation where a choice may be in the best interest of a child, but not in the best interest of other children in the family, the family as a whole, or the community. As described earlier, ethical frameworks of pediatric decision-making focus on the best interests of the child alone when weighing treatment options [52]. Such frameworks seek to highlight the primacy of the needs of the child and to protect the child from exploitation by those more powerful and hold that a child’s basic needs must always be met [4, 5, 9]. While intuitively appealing to pediatricians, such a stance overlooks that parents, siblings, and other caregivers are also moral agents with finite resources and pragmatically that even in the wealthiest countries public resources may be insufficient to meet the needs of children with kidney disease and their families [7]. Yet, it seems unfair for societal failures to support children and families to fall exclusively on the vulnerable child with kidney disease. The ethical tension between the needs of the child, other members of the family, and community in a setting of constrained resources does not offer a ready solution. It highlights a gap in the current ethical framework of pediatric medical decision-making. Recognition of this calls not only for advocacy from the pediatric nephrology community to appeal for greater supports for children and their families, but also for nephrologists to recognize the situation their patient and their patient’s families find themselves.

Systemic Injustice

Increasingly, it has been demonstrated that social determinants play a dramatic role in shaping health outcomes for children with CKD and their families. These include societal problems of structural racism, sexism, ableism, classism, and the biases associated with them which are experienced differently by particular individuals and groups within populations [53–55]. In addition, adverse environmental conditions and differences in access to healthcare experienced by particular groups can influence both the emergence and the progression of kidney disease [53]. This insight supports the need for critical reflection in clinical practice and research. For example, the use of race as a prognostic factor or association with an outcome of interest may overlook the impact of racism rather than race in influencing clinical outcomes [56–58]. The intersection between kidney disease and racial, ethnic, gender, and socioeconomic disparities further highlights how particular groups are disadvantaged [59]. Nephrologists should seek to become aware of the impact of social determinants of health and implicit biases and work to dismantle structural causes of inequity that impact the health and well-being of patients, families, and colleagues [55].

Further, it is incumbent upon nephrologists to recognize how historic injustices including colonialism and racism contribute to the inequities resulting in high rates of acquired kidney disease in children in low- and middle-income countries. This is seen through effects of environmental and poverty-related impacts including high prevalence of bacterial, viral, and parasitic infections, limited access to reproductive care, low birth weight, malnutrition, food insecurity, poor sanitation, unsafe water supply, and pollution all of which contribute to the development of kidney disease [38, 53, 60–62]. These injustices highlight the need for increased and sustained efforts to support children with kidney disease and those caring for them in the developing world as an integral part of pediatric nephrologists' roles as advocates and global citizens. Examples of such efforts include the training of and partnerships with pediatric nephrologists and allied professions practicing in low- and middle-income countries to better meet the needs of these populations [63]. Other examples include collaborative efforts such as the International Society of Nephrology's 0 by 25 initiative and the Saving Young Lives initiative supported by the International Pediatric Nephrology Association, International Society of Nephrology, International Society for Peritoneal Dialysis, and the Sustainable Kidney Care Foundation which focus on reducing child mortality and morbidity from acute kidney injury by establishing and maintaining centers for care of acute kidney injury and efforts to develop and maintain kidney disease registries [35, 38, 64–67].

Health Practitioner Bias

High-quality pediatric nephrology care requires tailoring recommendations to the needs of each individual child with kidney disease and their family. Such an approach may be as simple as prescribing a liquid form of a medication for a patient who cannot swallow pills or as complex as weighing the relative benefits of various therapies to a patient and family who face significant financial, social, and logistical challenges impeding optimal treatment. One challenge of individualized recommendations is that they can be influenced by the clinician's own perception of the challenges that a patient and their family face, and these perceptions can be influenced by practitioner bias. Bias is often characterized as: (1) explicit bias, in which the individual is aware of their feelings and attitudes that can influence their behavior, and (2) implicit bias, in which the individual is unaware of their feelings and attitudes that can influence their behavior. Bias of either type violates the principle of justice by incorporating factors that are not ethically relevant (ethnic background, class status, etc.) into the medical decision-making process.

Unfortunately, implicit bias is endemic in society and has been demonstrated in the medical care of nonmajority populations worldwide [68]. Pediatric providers are not immune from this phenomenon. Studies have demonstrated significant rates of implicit bias directed against both minority adults and children among practitioners [69, 70]. Such bias has been demonstrated to impact treatment recommendations in theoretical scenarios of pediatric care [71]. Although much of the research on implicit bias has been focused on bias against minority populations, implicit bias has the potential to affect the care of other disadvantaged groups.

Example: A Nonadherent Adolescent with Hypertension and Proteinuria[1]

A 16-year-old African American male receives care in an urban American pediatric nephrology clinic for hypertension and proteinuria in the setting of uncontrolled type 2 diabetes and obesity. He is a former preterm infant with low birth weight. Both of his parents have hypertension, diabetes, and obesity. After years of follow-up, the young man has made little progress in improving blood pressure or blood sugar control or losing weight. His physician expresses frustration due to the patient and his family's presumed nonadherence with recommendations and the resulting progression of disease.

While adherence with medical recommendations is critical in a successful therapeutic plan for any child, nonadherence is very common among children with chronic kidney disease, and pediatric nephrologists' perceptions of adherence may also be influenced by implicit biases including those related to race and socioeconomic status [54, 69, 72, 73]. Further, adherence with recommendations may be related to patient and family trust in their physician and more broadly in the medical establishment. In the United States, mistrust of the medical team within certain communities, including African Americans, may be well-founded and based upon historic episodes of exploitation of those communities.

In addition, while concerns for failure to adhere to diet, lifestyle, and medication recommendations may be perceived as a choice by the patient and/or their family and consequently that the adolescent and his family bear all or much of the responsibility for the patient's disease, we would urge nephrologists to recognize many systemic factors that may also be contributing. These factors include the effects of racist policies such as housing segregation that created unsafe neighborhoods and poverty, which can impact the ability to afford medications. The effects of these policies intersect with environmental injustice of lack of access to healthy food, food insecurity, and unsafe neighborhoods which limit access to healthy foods and opportunities for aerobic exercise. Further systemic injustice related to racism has been shown to contribute to preterm birth and low birth weight and lower nephron mass entailing an increased risk of hypertension, proteinuria, and progression of kidney disease.

The purpose of this example is not to deny moral agency to this patient and his family, but to highlight how unfair systemic forces outside the patient's control may also influence situations our patients find themselves in. This reinforces the importance of nephrologists maintaining an open mind, seeking to build supportive relationships, and working to advocate both for our individual patients and to address and dismantle the systemic forces that negatively influence our patient's health.

Abstract

As more than 60% of drugs are cleared by the kidneys, knowledge of drug handling and drug dosing in children with abnormal kidney function is essential. However, predicting drug clearance of drugs by the kidneys is not so straightforward. Very few drugs are actually cleared by glomerular filtration as this process requires that the drug to be unbound to plasma protein and an approprite size. Most drugs are actively transported into the lumen of the tubule and functionally, intact nephron endowment would be required for accurate drug clearance. Unfortunately, ways to assess nephron endowment are not clinically practical and therefore

glomerular filtration rate (GFR) remains the best surrogate marker of nephron endowment.

In this chapter we will discuss developmental changes of drug transport, how children handle drugs with normal and impaired kidney function, and general principles of drug dosing in children with chronic kidney disease (CKD). We will also cover drug dosing during renal replacement therapy.

Keywords

Pharmacokinetics · Pharmacodynamics · Drug transporters · Ontogeny · Filtration fraction · Nephron endowment · Creatinine · Cystatin C · Acute kidney injury · Drug toxicity · Antibiotics · AKI · Dialysis · Kidney replacement therapy

Abbreviations

AAG	Acid glycoprotein
AKI	Acute kidney injury
APD	Automated peritoneal dialysis
CAPD	Continuous ambulatory peritoneal dialysis
CAVHF	Continuous arterio-venous hemofiltration
CKD	Chronic kidney disease
CRRT	Continuous renal replacement therapies
CVVH	Continuous veno-venous hemofiltration
CVVHD	Continuous veno-venous hemodialysis
CVVHDF	Continuous veno-venous hemofiltration
CysC	Cystatin C
ERPF	Effective renal plasma flow
ESRD	End-stage renal disease
GFR	Glomerular filtration rate
HD	Hemodialysis
IHD	Intermittent hemodialysis
KDIGO	Kidney Disease: Improving Global Outcomes
PD	Peritoneal dialysis
RRF	Residual renal function
SCUF	Slow continuous ultrafiltration
SLED	Sustained low-efficiency dialysis
V_d	Volume of distribution

Background

The pattern of drugs used in children is different from adult populations because diseases and pathogen susceptibility undergo change with age. There are also substantial developmental changes of drug disposition [1]. There is a perception that drugs are rarely used in children. However, based on 1999–2014 National Health and Examination Survey, 21.9% of children and adolescents used any prescription drug in the past 30 days, while 8.5% used more than two drugs during the study period from 2011–2014. While the use of antibiotics and antihistamines decreased compared to the period 1999–2002, antihypertensives, asthma medications, attention-deficit hyperactivity disorder medications, proton pump inhibitors, antipsychotic, and contraceptive medications increased [2].

Off-label drug use is more prevalent in the pediatric population, referring to the use of pharmaceutical drugs for a different application, age group, dosage, or route of administration than their specific approval. This poses a problem as the ontogeny (developmental changes) of drug disposition has not been studied. For some specialized agents like antihypertensives, there are few pediatric formulations and for others, there are no pediatric studies to recommend a dose, therefore the adult dosage is extrapolated to children [3].

When using drugs in children it is important to consider all the factors involved in the drug-response relationship, including those related to pharmacokinetics and pharmacodynamics as well as prescription, adherence, and formulation details. There are important changes in drug bioavailability related to age, due to different pharmacokinetics (the absorption, distribution, metabolism, and elimination of drugs) and pharmacodynamics (the effects on the body), as well as developmental changes in body composition, distribution sites, gastrointestinal function, metabolic capacity, renal capacity, drug bioavailability, and metabolism. In general, the therapeutic index narrows in children [1, 4].

Drug metabolism can be performed by phase 1 or phase 2 reactions [5]. Phase 1 or nonsynthetic reactions comprehend oxidations, reductions, and hydrolysis and are mediated by enzymes mainly from p450 cytochromes, alcohol dehydrogenases, and aldehyde oxidases. Phase 1 reactions are involved in transforming drugs to more polar compounds for easy elimination through bile or urine, and inactivation or production of active or toxic metabolites. The expression of the different isoforms of cytochromes changes with age. Phase 2 reactions are also called synthetic and comprehend the conjugation with glucuronide (uridine-5-diphospho-glucuronosyltranspherase, UGT), sulphate (sulphate transpherase, SULT), glutathione (glutathione-S-transpherase), methylation (methyltranspherases), and acetic acid (acetyltranspherase). All of these compounds make more hydrophilic substances to facilitate clearance. Transporters are proteins located in different tissues of the apical and basolateral membranes, to facilitate the movement of compounds within the cell and from one compartment to another. They are crucial in pharmacokinetics because of their role in absorption and distribution of drugs, mainly against concentration gradient. Variations in the activity of transporters are extremely important for drug safety as they change with age, genetic polymorphisms, disease conditions, environmental factors, and drug interactions to modify drug clearance and toxicity [6, 7]. The kidneys express many transporters [8]. There is scarce information about the ontogenetic changes in the kidneys, but some models have been developed to predict toxicity of antibiotics in neonates, in whom the toxicity can vary depending upon postnatal age, gestational age, weight, and comorbidities [9].

Renal Clearance

The kidneys receive 25% of cardiac output beyond 18 months of life and are very active in biotransformation and clearance of drugs. There are substantial developmental changes in kidney function during the first 18 months of life [10]. Renal excretion of drugs relay upon filtration, active secretion/reabsorption, and passive diffusion. Free drug (not bounded to protein) is filtered by the glomeruli and undergoes reabsorption and secretion depending upon the drug transporters present.

Clearance is summarized as follows:

(Unbound drug × glomerular filtration rate (GFR)) + secretion-reabsorption [11].

However, most drugs have plasma protein binding, and their secretion depends on the number of functioning nephrons. Reabsorption of the drug along the proximal and distal tubules and the collecting ducts mitigate the drug's elimination from the body, both by filtration and by active secretion. Although reabsorption is primarily a passive process, it can have a profound impact.

Even though nephron endowment may be more important for drug clearance, we are not able to measure this directly, so we use GFR as a surrogate. Although inulin clearance is the gold standard, its use is challenging, especially in an acute setting; therefore, renal function is typically measured using endogenous markers [12]. Serum creatinine is the most commonly used endogenous marker but its use may be problematic in newborns [13].

Cystatin C [14], a different endogenous marker, may be more accurate for estimating renal function in children. Formulae that incorporate both cystatin C and serum creatinine are more robust in this age group [15]. Beta-trace protein, yet another marker, is believed to be a suitable alternative for newborns [16]. Nevertheless, these markers assess GFR rather than the effective renal plasma flow (ERPF), which would likely provide a better estimate of the kidneys' ability to excrete a drug [17]. For instance, hyperfiltration and changes in ERPF and filtration fraction all affect serum creatinine [18]. We recommend using the latest Schwartz formula, utilizing both cystatin C and creatinine for estimation of GFR [19].

Drug Properties and Dosing in Abnormal Kidney Function in Children

The most evident consequence of CKD is a decrease in the renal excretion of drugs. GFR-based adjustments are required if drugs are excreted through renal pathways per guidelines [20–23]. A less apparent effect of CKD on drug disposition is altered non-renal clearance

[24–27]. This can primarily be attributed to decreases in both hepatic drug metabolism and transporter-mediated biliary drug clearance [28]. Clinicians should avoid assuming that non-renally excreted drugs do not require a dose adjustment. Based on renal function level, Table 1 describes the drug dosing of commonly used antibiotics; Table 2 focuses on other antiorganisms; Table 3 on anticonvulsants; and Table 4 on immunosuppressants, diuretics, and other drugs. These tables are updates on the previous version of this book. Analgesics, antipyretics, and anti-inflammatory drugs can be used with caution, considering the potential nephrotoxicity of some drugs. Paracetamol and dipyrone are the most used analgesics in many countries since the renal toxicity is rare at therapeutic doses.

Drug Clearance in Dialysis

The physicochemical properties of a drug such as molecular size, protein binding, and volume of distribution largely determine its dialyzability. Additional factors specific to the dialysis prescription such as the type of dialyzer and blood/dialysate flow rates can also impact drug removal.

High-flux dialyzers can remove drugs with molecular weights of up to 40,000 Da. In practice, the pediatric nephrologist must ensure that references pertaining to dialytic drug clearance are current. For example, vancomycin (~1,450 Da) is minimally cleared with conventional dialysis but is extensively cleared with high-flux dialyzers (dialytic clearance between 45 and 131 ml/min with high-flux polysulfone dialysis membranes) [29, 30]. Other drugs that exhibit the same characteristic include carbamazepine, cisplatin, daptomycin, fluorouracil, ranitidine, and valproic acid [31].

The degree of plasma protein binding plays a large part in determining the degree to which a drug is removed by dialysis. Those with minimal protein binding are more likely to be removed by dialysis. Further complicating the impact of protein binding, kidney disease itself has been shown to affect the two major plasma proteins, albumin and alpha 1 acid glycoprotein (AAG). While dialysis patients often exhibit hypoalbuminemia, the inflammatory nature of CKD is thought to result in an increased concentration of AAG [32, 33]. Furthermore, uremic solutes that accumulate in CKD are known to increase the free fraction of some drugs, making them more easily dialyzable [34–38]. For example, uremic toxins are known to displace phenytoin from its binding sites on albumin, resulting in a greater free fraction of phenytoin available for removal by dialysis.

The volume of distribution of a drug also has a profound impact on its dialyzability. Drugs that have a small V_d (e.g., <0.7 L/kg) are generally restricted to the blood compartment and therefore more accessible for removal during dialysis. In contrast, drugs with a large V_d are distributed into the tissues and are generally minimally impacted by dialysis. Drugs with a large V_d are also more susceptible to the rebound effect following dialysis. Examples of drugs with a substantial rebound effect include gentamicin and vancomycin. Gentamicin concentrations rebound by up to 25% several hours following the completion of a dialysis session [39]. Vancomycin exhibits a similar rebound as plasma concentrations decrease by 38% immediately following dialysis but are only 16% lower than the predialysis concentration 5 h post-dialysis [40].

An excellent resource for drug dialyzability information is an annual publication by the Renal Pharmacy Consultants titled *Dialysis of Drugs* [31]. Despite the utility of this resource, many drugs lack information on this topic. Using *Dialysis of Drugs*, the authors determined that of all drugs surveyed for modern high-flux dialysis, only approximately 10% had clear evidence demonstrating whether they were dialyzable. An additional 40% were determined to be “likely” or “unlikely” to be dialyzed based on their physicochemical properties, with the remaining 50% of drugs having no information available [27]. Given the large proportion of drugs without data on drug dialyzability [27], it is important for the pediatric nephrologist to recognize the importance of the main factors that determine this characteristic such as size, protein binding, and volume of distribution, in order to rationally dose drugs in pediatric patients on hemodialysis.

Drug Removal During Intermittent Hemodialysis

Hemodynamically stable patients with poor renal function may be suitable candidates for intermittent hemodialysis (IHD). The excretion of renally cleared drugs is related to the residual renal function (RRF) of the patient. As such, only the dialyzability of a drug is considered when estimating dose adjustments for the IHD population. The RRF of the patient determines whether dose reduction or supplement dosing is required [41]. Since there is a lack of pediatric data, current recommendations on drug dosing in IHD patients are based largely on studies conducted in adults. Drug levels post-IHD may also guide treatment.

In 2011, the Kidney Disease Improving Global Outcomes (KDIGO) group held a conference to investigate the impact of renal replacement therapies on drug disposition. The following recommendations for drug dosing in IHD patients were developed: [20]

1. The drug dose should be given after the hemodialysis session (D_{HD}) to maintain active levels prior to subsequent dosing.
2. A supplemental dose should be given (D_{SUP}) in addition to the dose adjusted to renal failure (D_{FAIL}) to compensate for the fraction cleared through dialysis (Fr).

$$D_{\mathrm{HD}} = D_{\mathrm{FAIL}} + D_{\mathrm{SUP}}, \quad \text{where}$$

$$D_{\mathrm{SUP}} = \mathrm{Fr}(D_{\mathrm{START}} - D_{\mathrm{FAIL}})$$

One noteworthy limitation to the KDIGO primary recommendations is their derivation from low-flux nonsynthetic dialysis systems. Accordingly, they advise that the supplemental dose (DSUP) be increased for high-flux synthetic and/or high diffusive membranes.

Another important consideration in the IHD population is that the RRF, while presumed to be near zero, is not necessarily negligible. As a result, the predicted drug clearance in such patients may be underestimated [41]. For medications with a narrow therapeutic index, such as the aminoglycosides or vancomycin, therapeutic drug monitoring is indicated [20, 41]. When monitoring the plasma levels of such drugs, the following formula may be used to calculate the supplemental dose to be given, if requiered:

$$\text{Supplemental Dose} = (C_{\mathrm{DESIRABLE}} - C_{\mathrm{OBTAINED}}) \times V_d,$$

where $C_{\mathrm{DESIRABLE}}$ is the desired plasma concentration of the drug, C_{OBTAINED} is the concentration measured, and V_d is the volume of distribution.

Drug Removal and Dosing During Continuous Renal Replacement Therapies

Continuous renal replacement therapies (CRRT), where the fluids and solutes are continuously removed, are preferred for patients with acute kidney injury (AKI) or sepsis, who are unstable and in critical care units [42]. There are various techniques and strategies, including:

- Continuous arterio-venous hemofiltration
- Continuous veno-venous hemofiltration (CVVHF) [mostly convective clearance]
- Continuous arterio-venous hemodialysis, continuous veno-venous hemodialysis (CVVHD) [mostly diffusive clearance]
- Continuous arterio-venous hemodiafiltration (CAVHDF)
- Continuous veno-venous hemodiafiltration [mix of diffusive and convective clearance]
- Slow continuous ultrafiltration (SCUF) [mostly convective clearance]
- Sustained low-efficiency dialysis (SLED), sustained hemodiafiltration (S-HDF),
  and extended daily dialysis (EDD)

There have been a few studies examining the kinetics of various antibiotics used pediatric critical care units using systems rarely used in children [43–45]. The modality itself, the ultrafiltrate, the dialysate flow rates, the filter, and the patient's RRF may each have a significant impact on a drugs' pharmacokinetics [46].

Physicians often equate the drug clearance of all of the above-mentioned CRRT modalities at low rates of dialysate/ultrafiltrate production (<1 L/h). However, as the rate of ultrafiltrate/dialysate flow increases the difference between them, it becomes more apparent that dialytic-based mechanisms have the lowest solute clearance for a given flow rate.

Drug Clearance of CRRT Modalities : CVVHF > CVVHDF > CVVHD

The removal of drugs with CRRT is understudied, largely due to the vast number of drugs, the various modalities of CRRT, and the relatively small number of pediatric patients per CRRT modality. In general, a drug with a large V_d will be minimally impacted because of the low proportion of the total drug in the blood compartment. Total body water is 65–80% of the body weight in a child. Thus, a drug distributed well to all body compartments, would have a V_d of 0.7–0.8 L/kg. A drug with a V_d >0.8 L/kg would likely have additional tissue binding and CRRT would most likely remove little of the drug. Only the unbound fraction of a drug present in plasma water can be removed by CRRT.

Drugs with a high plasma protein binding (over 80%) including many antibiotics are poorly removed by CAVHD and CVVHD (mostly diffusive clearance), and only moderately cleared by CAVHDF and CVVHDF, as these have equal convective and diffusive clearance mechanisms. Many factors may affect unbound drug concentrations in critically ill children, including blood pH, heparin therapy, hypo-albuminemia, and the presence of fatty acids [47]. The reported plasma protein binding in healthy volunteers may substantially differ in critical care patients [48]. In summary, data on the dosage adjustment of drugs and their dialysability are limited because of a lack of clinical studies [48]. Existing guidelines mainly address antibiotics [48, 49]. In patients with AKI treated with CRRT, drug underdosing may lead to inadequate levels (especially for antibiotics), while overdosing may result in avoidable toxicities, which are often misdiagnosed as adverse drug reactions [47].

Drug Removal by Peritoneal Dialysis

Peritoneal dialysis (PD) is the preferred renal replacement therapy in pediatrics, particularly in small children. Using this technique, fluid and solute exchange occurs across the peritoneal membrane. The procedure may be performed throughout the day over the course of several hours, relying on gravity to force drainage (continuous ambulatory peritoneal dialysis [CAPD]) or through an external device that automatically cycles while the patient is asleep (automated peritoneal dialysis [APD]) [50]. While PD shares many of the principles of hemodialysis listed above, there are several notable drawbacks. The most clinically important difference is that drug clearance is less efficient through PD than through HD. A drug that is dosed appropriately for HD patients may be supratherapeutic for the PD population [51]. With the clearance capacity of PD in mind, the KDIGO group suggested that drug dosing in PD patients can be adapted from the dosing recommendations for patients with eGFR < 15 ml/min [20]. In effect, most PD patients may not require supplemental drug doses compared to other forms of renal replacement therapy.

One caveat, however, is that dosing may change between PD prescription modalities. Very few centers perform tidal dialysis and little data on drug clearance are known. CAPD provides a longer period of consistent drug removal compared to APD, while the latter provides a higher flow rate over a shorter time frame. Consequently, the drug-dosing regimen may differ depending on the PD modality. This necessity for changing drug dosing has been established for numerous drugs including vancomycin [52], cefazolin, and tobramycin [53]. Much like when estimating drug clearance in hemodialysis patients, a clinician must remain aware of the individual’s RRF, because it can result in subtherapeutic dosing.

Another drawback of PD is peritonitis. In 2012, a consensus guideline released by Warady et al. suggested that the intraperitoneal (IP) route be used for antibiotic treatment administered for bacterial peritonitis [54]. Many of the above-mentioned factors concerning drug dialyzability also apply when dosing drugs via IP administration. While there is a paucity of data in children with regard to drug clearance following IP administration, ongoing research is attempting to reconcile pediatric and adult data.

Nephrotoxicity

The kidneys are able to concentrate and eliminate endogenous and exogenous toxic compounds. In some drugs, renal toxicity can be predicted with models that evaluate in vitro necrosis and apoptosis. There is no consensus definition of drug nephrotoxicity, making it difficult to diagnose, report, and compare outcomes. In nephrotoxicity, all nephron segments can be damaged, and there are acute and chronic phenotypes. The definition of acute kidney injury considers serum creatinine and urinary volume, however, sometimes the tubular damage is more important and serum creatinine alone does not allow case detection. Metha and coworkers proposed a phenotype standardization for drug-induced kidney toxicity, which can be presented in one of four phenotypes: acute kidney injury, glomerular disorder, tubular disorder, or nephrolithiasis/crystalluria [55]. A single drug can cause more than one damage phenotype and both, neonates and hospitalized patients are more susceptible to drug-induced renal toxicity.

Conclusions

More than 60% of drugs are cleared by the kidneys and while most are actively transported into the lumen of the tubules, very few drugs are cleared by glomerular filtration due to molecular size and no plasma protein binding. Accurate drug clearance requires intact nephron endowment and accurate renal function measurement.

During acute kidney injury, CKD or ESRD, drug dosing is a dynamic process that is dictated by drug levels, renal replacement therapy, or residual renal function. Drug dosing in patients with renal replacement therapy is determined by the treatment modality. Clinicians should be aware that CKD can affect the metabolism of non-renally excreted drugs.

	17 to <19 years	0.69–1.10	0.60–0.88

Formulas for GFR assessment:

A. Creatinine-based estimated GFR (eGFR) equations

- ***Schwartz equation*:**

  Using Jaffe assay (1976) [33, 34]: eGFR = k × height/Scr

  (*where height is in cm, Scr in mg/dL, and k depends on age: k = 0.33 for preterm infants throughout the first year of life; k = 0.45 for term infants throughout the first year of life; k = 0.55 for children and adolescent girls; k = 0.7 for adolescent boys* (*≥13 years old*))

  Using enzymatic assay (2009) [35]: eGFR = 0.413 × height/Scr

  (*where height is in cm, Scr in mg/dL*)

(continued)

- ***Pottel eq.*** (2012) [36]:
  $\text{eGFR} = 107.3/(\text{Scr}/Q)$
  (*where Q is the median Scr for healthy children of a particular age*)
- Gao quadratic formula (2013) [37]:
  Females: $0.68 \times (\text{Height}/\text{Scr}) - 0.0008 \times (\text{height}/\text{Scr})^2 + 0.48 \times \text{age} - 21.53$
  Males: $0.68 \times (\text{Height}/\text{Scr}) - 0.0008 \times (\text{height}/\text{Scr})^2 + 0.48 \times \text{age} - 25.68$
  (*where height is in cm, Scr in mg/dl, age in years*)

B. Cystatine C-based eGFR equations

- ***Zappitelli*** (2006) [38]:
  $\text{eGFR} = 75.94 \times \text{CysC}^{-1.17}$ if renal transplant, × 1.2
- ***Schwartz eq.*** (2012) [39, 40]:
  $\text{eGFR} = 70.69 \times (\text{CysC}^{-0.931})$
  (*If using a cystatin C platform based on the ERM_DA471/IFCC reference material, dividing IFCC-calibrated cystatin C levels by 1.17 and using this value in the equations listed above has been suggested*)

C. Combined creatinine and cystatin C equations

- ***Zappitelli*** (2006) [38]:
  $\text{eGFR} = (43.82 \times \exp.(0.003 \times \text{height}))/(\text{CysC}^{0.635} \times \text{Scr}^{0.547}) \times 1.165$ if renal transplant and $\times 1.57\text{Scr}^{0.925}$ if spina bifida (*where Scr is in mg/dl*)
- ***Schwartz*** (***CKiD***, 2009) [41]**:**
  $\text{eGFR} = 39{,}1 \times (\text{talla}/\text{Scr})^{0{,}516} \times (1{,}8/\text{CysC})^{0{,}294} \times (30/\text{BUN})^{0{,}169} \times 1{,}099^{\text{varón}} \times (\text{height}/1{,}4)^{0{,}188}$
  (*where height is in m, Scr in mg/dl, CysC in mg/l, and BUN in mg/dl*)
- ***Schwartz***, (***CKiD***, 2012) [39, 40]:
  $\text{eGFR} = 39.8 \times [\text{height}/\text{Scr}]^{0.456} \times [1.8/\text{Cys C}]^{0.418} \times [30/\text{BUN}]^{0.079} \times [1.076]^{\text{male}} \times [\text{height}/1.4]^{0.179}$
  (*where height is in m, Scr in mg/dl, Cys C in mg/L, and BUN in mg/dl. If using a cystatin C platform based on the ERM_DA471/IFCC reference material, dividing IFCC-calibrated cystatin C levels by 1.17 and using this value in the equations listed above has been suggested*)
- ***Chehade*** (2014) [42]:
  Female patients: $0.42 \times (\text{Ht}/\text{SCreat}) - 0.04 \times (\text{Ht}/\text{SCreat})^2 - 14.5 \times \text{CysC} + 0.69 \times \text{age} + 18.25$
  Male patients: $0.42 \times (\text{Ht}/\text{SCreat}) - 0.04 \times (\text{Ht}/\text{SCreat})^2 - 14.5 \times \text{CysC} + 0.69 \times \text{age} + 21.88$
  (*where Ht is in cm, SCreat in mg/dl, CysC in mg/L, and age in years*)

Glomerular filtration rate (mL/min/1.73 m^2) (GFR) [43]	**Preterm**		
	7 days	19.9 ± 9.3	19.9 ± 9.3

	>1 year	132–140	132–140
Total calcium (mmol/L) [1]	0 to <1 year	2.13–2.74	2.13–2.74
	1 to <19 years	2.29–2.63	2.29–2.63

*Normal ranges values are given as International System (SI) units. For conversion to Conventional (CON) units, please refer to online conversion resources [10]

Urine Studies and Tubular Function*

Urinary anion gap	Age range	Male	Female
Anion gap (mmol/L) [61, 62, 63]	Neonates (not reliable)	N/A	N/A
	Infants-adult	without acidosis: 23–95	without acidosis: 23–95
		with acidosis: −67 to −5	with acidosis: −67 to −5
Urinary acute kidney injury biomarkers			
IL-18 (pg/ml) [64]	3 to <5 years	<78.3	<100.5
	5 to <10 years	<41.7	<79.0
	10 to <15 years	<58.5	<111.1
	15 to <18 years	<71.2	<273.1
KIM-1 (ng/ml) [64]	3 to <5 years	<983.7	<1291.7
	5 to <10 years	<1276.6	<1212.9
	10 to <15 years	<1156.6	<1103.5
	15 to <18 years	<1876.2	<1934.5
LFABP (ng/ml) [64]	3 to <5 years	<49.4	<41.4
	5 to <10 years	<15.5	<13.5
	10 to <15 years	<13.7	<13.3
	15 to <18 years	<10.5	<6.7
NGAL (ng/ml) [64]	3 to <5 years	<26.1	<52.2
	5 to <10 years	<10.9	<139.5
	10 to <15 years	<22.5	<72.3
	15 to <18 years	<50	<138.6
NGAL [65]: cutoff values to predict AKI have generally ranged from 100–270 ng/mL. In children, a pooled analysis showed a cutoff of 135 ng/mL has shown a 77.6% sensitivity and 88.0% sensitivity to predict AKI			
TIMP2-IGBP7 (ng/ml)^2/1000 ([66])	0–28 days	0.08–0.27	0.08–0.27
	29 days to 2 years	0.02–0.25	0.02–0.25
	2–5 years	0.20–0.84	0.20–0.84
	6–11 years	0.26–1.07	0.26–1.07
	12–18 years	0.07–0.46	0.07–0.46
TIMP2-IGBP7 [67]: cutoff values to predict AKI are as follows: ≤0.3, low risk; >0.3 and ≤2.0, moderate risk; and >2.0, high risk			

(continued)

Urinary anion gap	Age range	Male	Female

	18–29 years	190–583	142–510
Urinary catecholamines: values are reported for Mayo Clinic Laboratories (Rochester, MN) [69, 70] individual laboratory assays may vary. Sensitivity and specificity for urine catecholamines differ based on cutoff used. To increase specificity, higher cutoffs than the established reference ranges in healthy populations have been used: norepinephrine >170 mcg/24 h, epinephrine >35 mcg/24 h, dopamine >700 mcg/24 h, normetanephrine >900 mg/24 h, and metanephrine >400 mcg/24 h, total metanephrines >1300 mg/24 h Using combined 24 h metanephrines and catecholamines (positive test defined as either urine metanephrines or any catecholamine is elevated) has resulted in a sensitive and specificity of 98% [71, 72]			
Urine creatinine excretion, pH, and maximum osmolality			
Maximum osmolality (mOsm/L) [45]	10–30 days	775–963	775–963
	1–2 months	963–1051	963–1051
	2–6 months	1051–1156	1051–1156

Urinary anion gap	Age range	Male	Female
24-h urine citrate (mg/day) [74] **To convert to mmol/day: multiply by 0.005205	2–7 years	67–659	87–734
	7–13 years	102–989	162–1067
	13–18 years	130–1328	231–1589
Urine citrate/creatinine ratio (mg/g creatinine) [74] **To convert to mmol/mol: multiply by 0.589	2–7 years	243–1778	290–2370
	7–13 years	139–1212	261–1462
	13–18 years	87–976	216–1404
Calcium to citrate ratio (mg/mg) [74] **To convert to mmol/mmol: multiply by 4.79	2–7 years	0.05–0.48	0.03–0.42
	7–13 years	0.05–0.60	0.04–0.47
	13–18 years	0.06–0.80	0.05–0.60
Assessment of nephrolithiasis [74, 78]: hypocitraturia has usually been defined as a citrate/creatinine ratio (mg/g) of <180. Cutoff values normalized to body surface area are less age dependent, and values of 180 mg/1.73m^2/day (males) and 250 mg/1.73m^2/day (females) have been suggested. The calcium to citrate ratio has also been used in the assessment of nephrolithiasis, with a value of 0.326 providing good discrimination between normal controls and children with nephrolithiasis			
24-h urine magnesium (mg/kg/day) [79] **To convert to mmol/kg/day: multiply by 0.0411	3–5 years	1.1–3.8	1.1–3.8
	6–8 years	1.0–4.0	1.0–4.0
	9–11 years	0.4–3.4	0.4–3.4
	12–14 years	0.4–3.3	0.4–3.3
	15–16 years	0.5–3.0	0.5–3.0
Urine magnesium/creatinine ratio (mg/mg) [76] **To convert to mmol/mmol: multiply by 4.65	1 month to 1 year	0.10–0.48	0.10–0.48
	1–2 years	0.09–0.37	0.09–0.37
	2–3 years	0.07–0.34	0.07–0.34
	3–5 years	0.07–0.29	0.07–0.29
	5–7 years	0.06–0.21	0.06–0.21
	7–10 years	0.05–0.18	0.05–0.18
	10–14 years	0.05–0.15	0.05–0.15
	14–17 years	0.05–0.13	0.05–0.13
Oxalate (24-h collection) [80]	all ages	<45 mg/1.73m^2/day (<0.50 mmol/1.73m^2/day	<45 mg/1.73m^2/day (<0.50 mmol/1.73m^2/day
Urine oxalate/creatinine ratio (mg/mg) [81] **To convert to mmol/mmol: multiply by 1.255	1 month to 6 months	0.056–0.175	0.056–0.175
	6 months to1 year	0.048–0.139	0.048–0.139
	1–2 years	0.040–0.103	0.040–0.103
	2–3 years	0.032–0.080	0.032–0.080
	3–5 years	0.024–0.064	0.024–0.064
	5–7 years	0.024–0.056	0.024–0.056
	7–17 years	0.016–0.048	0.016–0.048
Hyperoxaluria: There is no clear cutoff for primary versus secondary hyperoxaluria. Urinary excretion greater than 0.7 mmol (63 mg)/1.73m^2/day is more likely to have a metabolic cause. Reference ranges may vary based on laboratory assay used			
Urinary glycolate/creatinine ratio (mg/g) [80] **To convert to mmol/mol: multiply by 1.507	0–6 months	<241–282	<241–282
	7–24 months	<163–194	<163–194
	2–5 years	<127–152	<127–152
	5–14 years	<110–123	<110–123
	>16 years	<66–83	<66–83

(continued)

Urinary anion gap	Age range	Male	Female
Urinary L-glycerate-to-creatinine ratio (mg/g) [80] **To convert to mmol/mol: multiply by 1.066	0–6 months	<13–193	<13–193
	7–24 months	<13–193	<13–193
	2–5 years	<13–193	<13–193
	5–14 years	<22–129	<22–129
	>16 years	<129	<129
Increased concentrations of oxalate and glycolate indicate type 1 hyperoxaluria; increased concentrations of oxalate and glycerate indicate type 2 hyperoxaluria. Reference ranges may vary based on performing laboratory			
Uric acid (24-h collection) [82]	>2 years	<815 mg/1.73m^2/day (<4.85 mmol/1.73m^2/day)	<815 mg/1.73m^2/day (<4.85 mmol/1.73m^2/day)
Urine uric acid/creatinine ratio (mg/mg) [80] **To convert to mmol/mmol: multiply by 0.673	1 month to 6 months	1.189–2.379	1.189–2.379
	6 months to 1 year	1.040–2.229	1.040–2.229
	1–2 years	0.743–2.080	0.743–2.080
	2–3 years	0.689–1.932	0.689–1.932

	5–7 years	0.446–1.189	0.446–1.189
	7–10 years	0.386–0.832	0.386–0.832
	10–14 years	0.297–0.654	0.297–0.654
	14–17 years	0.297–0.594	0.297–0.594
½ Cystine µmol/g creatinine [68] (reported as ½ Cystine because initial methods of quantification involved a reduction of cystine followed by an assay for cysteine) **To convert to µmol/mmol creatinine: multiply by factor of 0.113	0–1 month	212–690	212–690
	1–6 months	115–424	115–424
	6–12 months	106–256	106–256
	1–2 years	88–230	88–230
	2–4 years	71–265	71–265
	4–7 years	71–194	71–194
	7–10 years	71–186	71–186
	10–13 years	62–203	62–203
	>13 years	53–301	53–301
Cystine µmol/g creatinine (reported as cystine) [83] **To convert to µmol/mmol creatinine: multiply by factor of 0.113	< or = 12 months	12–504	12–504
	13–35 months	11–133	11–133
	3–6 years	<130	<130
	7–8 years	<56	<56
	9–17 years	<104	<104
	> or = 18 years	10–98	10–98
Cystinuria [84]: Assays may vary between laboratories. Children with cystinuria generally have markedly elevated urinary cystine levels, with values >1300 µmol/g, but the amount can vary markedly with some having values exceeding 3000. More mild elevations can be seen in asymptomatic heterozygote carriers of type B cystinuria			
Urine microscopy			
Cells (RBC/hpf) [85, 86]	Birth to 18 years	0–4 RBC/HPF (centrifuged)	0–4 RBC/HPF (centrifuged)
	Birth to 18 years	0–5 RBC/mm^3 (uncentrifuged)	0–5 RBC/mm^3 (uncentrifuged)
Cells (WBC/hpf) [87]	Birth to 18 years	0–4 WBC/HFP (centrifuged)	0–4 WBC/HFP (centrifuged)
	Birth to 18 years	0–9 WBC/mm^3 (uncentrifuged)	0–9 WBC/mm^3 (uncentrifuged)

(continued)

Urinary anion gap	Age range	Male	Female
Urine protein			
B2-microglobulin/creatinine ratio (μg/g) [88, 89]	all ages (random)	≤300 μg/g	<300 μg/g
Microalbuminuria (mg albumin/ gm creatinine) [90, 91]	10–18 years	30 mg/g	30 mg/g
Spot urine protein/creatinine ratio (mg/mg) [90, 92]	6–24 months	<0.5	<0.5
	>2 years	<0.2	<0.2
Urinary protein (24-h urine collection) [90]	1–18 years	<100 mg/m^2/day	<100 mg/m^2/day
Tubular function assessment			
Magnesium fractional excretion (FeMg) (%) [93]	All ages	0.5–4	0.5–4
Magnesium fractional excretion [94]: FeMg formula: [(Mg urine × Scr)/(0.7 × Mg plasma × Cr urine)] × 100 The factor of 0.7 adjusts total plasma Mg concentration to the freely filtered fraction A FeMg >4% is consistent with renal Mg wasting, while a FeMg <2% is consistent with an extrarenal origin of hypomagnesemia. The evaluation has to be made with normal Mg serum values			
Tubular maximum reabsortion for phosphate corrected for GFR (TmP/GFR) (mmol/l) [95]	2 to <4 years	1.04–2.79	1.04–2.79
	4 to <6 years	1.05–2.60	1.05–2.60
	6 to <8 years	1.26–2.35	1.26–2.35
	8 to <9 years	1.1–2.31	1.1–2.31
	10 to <12 years	1.15–2.58	1.15–2.58
	12 to <15 years	1.18–2.09	1.18–2.09
Tubular maximum reabsortion for phosphate corrected for GFR [96] [97]: TmP/GFR formula = {1-[(Urine p × Serum cr)/Urine cr × Serum p)]} × Serum p (where p: phosphate, cr is creatinine) In children, TmP/GFR is identical to formula TP/GFR = [Sp – (Up × Scr)/Ucr] which represents tubular phosphate reabsortion under fasting or nonfasting conditions without phosphate load			
Fractional excretion of sodium (FeNa) [98]	All ages	<1%	<1%
Fractional excretion of sodium [98]: Formula for FeNa is as follows: FeNa = [(Na urine x Scr) × 100]/(Na plasma × Cr urine) A FeNa <1% is suggestive of prerenal disease, whereas a value >2% indicates acute tubular necrosis. However, FeNa may perform poorly in several disease states, including glomerulonephritis, urinary obstruction, and nonoliguric ATN			
Fractional excretion of urea [98]	All ages	<35%	<35%
Formula for fractional excretion of urea (FeUrea) [98]: FeUrea = (Urea urine × Scr)/(Urea plasma × Cr urine) A FeUrea <35% is suggestive of prerenal disease, whereas a FeUrea >50% is indicative of AKI. However, this test may have limited utility in many patients with hospital-acquired AKI			
Transtubular potassium gradient [99]	All ages (in hyperkalemic state)	>6	>6
	All ages (in hypokalemic state)	<2	<2
Formula for transtubular potassium gradient (TTKG) [99]: TTKG = (K urine × Osm blood)/(K plasma × Osm urine) Generally, a TTGK of <6 is considered indicated of impaired K secretion during hyperkalemia. Conversely, a TTKG >2 is considered inappropriate during hypokalemia. TTKG requires urine Na to be >25 meq/L and a urine osmolality that is equal to or greater than the serum osmolality			

[*] Normal ranges values are given as International System (SI) units. For conversion to Conventional (CON) units, please refer to online conversion resources [10]

[**] Conventional units are reported as reference ranges, given their most frequent clinical use. Conversion factors to SI units are included for each analyte
